Treatment of Tetanus by Subdural Injections of Antitoxin.—A. W. Elting² reports 3 instructive cases. The first was a case of puerperal tetanus in a woman of 35, the incubation period being 9 days. The patient received about 1,200 cc. of tetanus antitoxin subcutaneously and 150 cc. subdurally. The latter was given in 3 doses of 50 cc. each during a period of 27 hours by means of ordinary lumbar puncture. Each time this

¹ Reference Handbook of the Medical Sciences, Vol. vii, p. 85.

² Albany Medical Annals, January, 1904.

measure was resorted to the patient seemed in *extremis*, and each time there was great improvement in all the symptoms in from 1 to 3 hours after the injection. These large doses were without the least untoward effect. Recovery followed, and Elting firmly believes that the patient's life was saved by the subdural injections. The other 2 cases were both acute; treatment was not instituted until 36 hours after onset of symptoms, and death ensued in each instance. In one the temporary beneficial effect of subdural injection of antitoxin was very pronounced, while in the other it gave little relief. Autopsy in one showed that the injection of 50 cc. had produced no demonstrable anatomic lesion. The last 2 cases resulted from nail wounds of the foot, but no tetanus bacilli were found either by culture or inoculation of animals. A distinct local tetanus occurred in the leg of one of these patients, the spasms not relaxing under ether when the wound was excised. Elting believes that the antitoxin treatment is productive of better results than is any other method. Large quantities should be available for inoculation, but this too often is not the case. [A.G.E.]

Effects of Aspidospermin upon Respiration and Circulation.—H. C. Wood, Jr., and D. M. Hoyt¹ found that aspidospermin caused in the dog a very marked increase in the activity of respiration, the amount of air moved as measured by a special gasometer being increased in some experiments as much as 400%. The respirations were deeper and more rapid. The percentage of carbonic acid expired was slightly reduced although the total amount exhaled was considerably above normal. The observation of Penzoldt that the blood all over the body assumed the arterial hue, they noted in several but not all of their experiments. They believe the blood changes however, to be the result of increased respiration and not the cause. Repeated spectroscopic examination of the blood failed to reveal any new compound. The blood in aspidospermin poisoning does not lose the power to change the color of guaiac solutions and is capable, if the supply of oxygen is shut off from the animal, of giving off its oxygen to the tissues. The blood-pressure was reduced by aspidospermin, probably, Wood and Hoyt believe, by direct action on the cardiac muscle, as they found the vasomotor system not affected. Their experiments were made with the commercial amorphous aspidospermin which contains, as is well known, several alkaloids, and probably represents the whole activity of the aspidosperma quebracho blanco. [H. C. W.] [The clinical value of aspidospermin in many cases of asthma receives illumination from these researches. S.S.C.]

Treatment of Strangulated Hernia with Atropin.—According to Hagen,² the current views on strangulated hernia cannot be maintained. He believes that a reflex spasm of the abdominal muscles surrounding the hernial ring is responsible for the strangulation. The real cause lies in a paresis of the muscular coats of the bowel, preventing normal peristalsis, and bringing about an accumulation of intestine in the hernial sac. Also, in opposition to the view that atropin paralyzes smooth muscle fibers, he has found that small doses stimulate the sympathetic nerve endings in the iris and intestine, also the vagus fibers of the heart and intestine. He has therefore evolved a treatment for strangulated hernia, consisting in the injection in the immediate neighborhood of the sac, of .5 cc. (8 minims) of a 1 to 1000 solution of atropin; this is followed by light taxis. If unsuccessful, the dose is repeated at intervals of an hour, with the taxis. A double dose may be given, if deemed necessary. If no improvement is noted after 2 or 3 trials, or if the condition becomes worse, herniotomy can always be resorted to. Care must be taken not to wound the intestines by the hypodermic needle, and also to prevent so far as possible the systemic absorption of the atropin. [B.K.]

Treatment of Ankylostomiasis by Filmaron.—Filmaron is the nontoxic active principle of male fern, and in Nagel's opinion³ the part of male fern which benumbs the tapeworm; to remove the worm an active purge is always necessary. He has used the drug successfully in 9 cases, in which filix mas and thymol were used without success. Filix mas has been known to produce sudden blindness, and the discovery of its

active, nontoxic principle, therefore, will be a boon for regions in which ankylostomiasis is common. [E.L.]

The Use of Adrenal Extract in Gastrointestinal Atony.—Baccarani and Plessi¹ have obtained good results with an extract prepared from the medulla of the suprarenal capsules in the treatment of atony of the stomach. They reason that it has the same effect upon the nonstriated muscle of this organ as it has upon the bloodvessels, and they employed it in a number of cases with a certain proportion of immediate results. Experimental observations show an increase in the motility of the stomach. [H.C.W.]

The Treatment of Sciatica with Strychnin.—Encouraged by the report of Tchawoff at the Second Bulgarian Medical Congress, F. O. Sartsin² began to treat sciatica with hypodermic injections of strychnin. The nitrate was employed in doses of 1 mg. to 2 mg. ($\frac{1}{100}$ gr. to $\frac{2}{100}$ gr.) injected into the gluteal region at intervals of one to several days. Nine patients were thus treated; in 4 the attacks of pain disappeared; 3 patients were benefited; but not cured, while 1 patient suffering from sciatica and lancinating pains was relieved of the sciatica but not of the lancinating pains. Sartsin confidently declares strychnin to be the most efficient agent so far recommended against sciatica. [L.J.]

Therapeutic Use of Nafalan.—This is a new preparation made from naphtha and soap, and is closely related to naftalan, a therapeutic soap. S. Wischnowitz³ has found it a valuable, nonirritant, antiphlogistic, analgesic substance, greatly promoting resorption of cutaneous inflammatory infiltrations. It is efficacious in eczema, pityriasis versicolor, impetigo, herpes zoster, frost-bite, burns, röntgen ray dermatitis, and pruritus. It may also be used in articular rheumatism, epididymitis, sciatica, and tenosynovitis. It should not be employed in fresh, acute, moist eczemas. One of the best forms in which to employ nafalan is in a 50% ointment with zinc ointment, paraffin, and lanolin. It is best applied on a cloth, which is laid over the affected part. Wischnowitz has found nafalan very useful in the treatment of hyperidrosis, in which affection he first employs it in the pure state, and after desquamation occurs, in a 10% dusting powder. In burns and röntgen ray dermatitis it is also applied pure. In herpes zoster it may be employed in varying strengths, according to the severity of the symptoms. [B.K.]

Lead-poisoning or Mercurialism an Indication for Calcium Sulfid.—Enrique L. Abogado⁴ believes with Pigeau and Peyrou that workers in quicksilver mines should be administered regular doses of calcium sulfid; for it has been found by tests on syphilitic patients to increase the elimination by the kidneys of both mercury and lead. Each day's dose at first should be .20 gm. divided, and increased or diminished according to gastric tolerance. [T.H.E.]

Action of Strychnin in Polyuria and Diabetes Insipidus.—L. Feilchenfeld⁵ reports considerable diminution in the quantity of urine in 2 cases of polyuria and diabetes insipidus without change in the specific gravity, after hypodermic injections of strychnin nitrate 2.5 mg. to 5 mg. ($\frac{1}{20}$ gr. to $\frac{1}{10}$ gr.) daily. He supposes this is due to a direct action on the central nervous system on account of the promptness of the action and the absence of change in specific gravity.

Phototherapy in the Healing of Wounds.—Bieling⁶ recommends the use of light as a stimulant to the healing process of wounds, especially those in which there are large defects in the skin. He reports a case following abdominal operation in which there remained a space of granulation tissue about the size of a bean, over which, despite various methods of treatment, the skin refused to form. With 5 exposures to light there was an immediate stimulation of the epidermic growth, and closure of the wound. In another case following a crush of the shin, there remained a defect in the skin the size of the palm of the hand, which rapidly healed under the use of phototherapy. [H.C.W.]

Changes in the Medical Corps of the U. S. Army for the week ended January 30, 1904:

HUTTON, First Lieutenant PAUL C., assistant surgeon, is relieved from duty at Pekin, China, and will proceed to Fort Bayard and report at the United States Army General Hospital for duty.

WATERHOUSE, M. MANLEY, contract surgeon, now at San Francisco, Cal., en route to the Philippine Islands, will report to the commanding general, department of California, for temporary duty and for assignment to duty with the first detachment of troops to be sent from San Francisco to an eastern station. Upon his arrival at such station and the completion of the duty assigned to him, Contract Surgeon Waterhouse will proceed to his home, New York City, for annulment of contract.

PATTEN, First Lieutenant I. W., assistant surgeon, is granted leave for one month.

So much of orders of January 13 as relate to First Lieutenant Haywood S. Hansell, assistant surgeon, are so amended as to direct him to proceed to Pekin, China, and report to the commanding officer, United States Legation Guard, for duty.

KIRBY-SMITH, First Lieutenant REYNOLD M., assistant surgeon, is granted leave for twenty days from January 27, with permission to apply for an extension of seven days.

TURNBULL, First Lieutenant WILFRED, assistant surgeon, is relieved from duty at Fort Monroe, and will proceed to Fort Strong for duty, to relieve Captain Elmer A. Dean, assistant surgeon. Captain Dean will proceed to Fort Riley for duty.

PORTER, LEWIS B., contract surgeon, is relieved from duty at the United States Army General Hospital, Presidio, and will proceed to his home, New Haven, Conn., for annulment of contract.

Changes in the Medical Corps of the U. S. Navy for the week ended January 30, 1904:

ARNOLD, W. F., surgeon, sick leave extended two months—January 23.

SPEAR, R., passed assistant surgeon, ordered to the Naval Hospital, Washington, D.C.—January 25.

SHIPP, E. M., passed assistant surgeon, ordered to the Naval Hospital, New York—January 25.

STONE, M. V., assistant surgeon, retired from active service on account of disability incident to the service—January 27.

PAYNE, J. H., JR., passed assistant surgeon, detached from the Wabash and ordered to the Naval Hospital, San Juan, P. R.—January 23.

MORSE, E. T., pharmacist, detached from the Navy Yard, Portsmouth, and ordered to the Naval Laboratory—January 25.

Changes in the Public Health and Marine-Hospital Service for the two weeks ended January 23, 1904:

WERTENBAKER, C. P., passed assistant surgeon, granted leave of absence for five days from January 21—January 23, 1904. Detailed to make inspection of places in Mexico and the Texas border recently infected with yellow fever—January 23, 1904.

ROSENAU, M. J., passed assistant surgeon, one day's leave of absence, January 16, 1904, under paragraph 189 of the regulations.

GREENE, J. B., passed assistant surgeon, granted leave of absence, on account of sickness, for fifteen days from January 26—January 25, 1904.

VON EZDORE, R. H., passed assistant surgeon, granted leave of absence for thirteen days from January 25—January 23, 1904.

ANDERSON, J. F., passed assistant surgeon, granted leave of absence for six days from January 25, 1904, under paragraph 191 of the regulations.

MCCLINTIC, T. B., assistant surgeon, granted leave of absence for six days from January 25, 1904, under paragraph 191 of the regulations.

FOSTER, S. B., acting assistant surgeon, granted leave of absence for ten days from January 17—January 16, 1904.

SCHUG, F. J., acting assistant surgeon, granted leave of absence December 22, 1903, to January 5, 1904, on account of sickness—January 25, 1904.

WALKER, R. T., acting assistant surgeon, leave of absence granted for twenty days from January 13, 1904, revoked—January 21, 1904.

ALLEN, G. C., pharmacist, upon being relieved from temporary duty at Louisville, Ky., by Pharmacist G. C. Ferdinand, to rejoin station at New Orleans, La.—January 26, 1904.

HOLT, F. M., pharmacist, relieved from duty at Louisville, Ky., and directed to proceed to Washington, D. C., and report at Bureau for temporary duty—January 13, 1904.

FERDINAND, G. O., pharmacist, to proceed to Louisville, Ky., and report to the medical officer in command for duty and assignment to quarters—January 26, 1904.

Boards Convened.

Board convened to meet at the Bureau, January 25, 1904, for the physical examination of officers for promotion and applicants for admission into the Revenue Cutter Service. Detail for the Board: Assistant Surgeon-General W. J. Pettus, chairman; Assistant Surgeon A. J. McLaughlin, recorder.

Board convened to meet at the Marine Hospital, Port Townsend, Wash., February 1, 1904, for the physical examination of an officer of the Revenue Cutter Service. Detail for the Board: Passed Assistant Surgeon J. H. Oakley, chairman; Passed Assistant Surgeon M. H. Foster, recorder.

Board convened to meet at Washington, D. C., January 26, 1904, for the physical examination of such officers of the Revenue Cutter Service and applicants for admission thereto as may present themselves. Detail for the Board: Assistant Surgeon-General L. L. Williams, chairman; Assistant Surgeon A. J. McLaughlin, recorder.

Promotions.

Assistant Surgeons W. C. Billings, J. W. Kerr, and G. M. Corput commissioned as passed assistant surgeons, to rank as such from December 29, 1903, December 31, 1903, and January 6, 1904, respectively—January 12, 1904.

Appointment.

George O. Ferdinand, of New York, appointed pharmacist of the third class—January 21, 1904.

PUBLISHED WEEKLY AT 1321 WALNUT STREET PHILADELPHIA BY THE AMERICAN-MEDICINE PUBLISHING COMPANY

VOL. VII, No. 7.

FEBRUARY 13, 1904.

\$5.00 YEARLY.

Vaccination a Condition of Entrance to Almshouses, Hospitals, etc.—The authorities of the Philadelphia Hospital have made it a rule that no inmates will be received at the almshouse and hospital unless there have been recent vaccinations, or the patients are willing to be vaccinated at once. More than 5,000 are given treatment, food and lodging at the institution, and if smallpox were not prevented the place might at least become a source of great public danger. Is this capital rule in existence in many or in most institutions of the kind in the United States? The taxpayers have a right to demand it, and the profession through its influence could undoubtedly secure the enactment and execution of the necessary laws. One caution is necessary; the antivaccinationists must not be allowed to defeat the preventive measure by nitric acid sores or other scars made to deceive. If there is no way of detecting the fraud some methods of lessening it should be devised. Should not test questions, and even affidavits, be demanded by the examiners?

Does the Pay-Patient Department Pay?—In its first annual report that excellent institution *The Hospital Association of Philadelphia* gives the answers made by a number of hospitals to a list of suggestive and important questions. Among them was this:—

Is the pay-patient department a profitable one?

The answers were as follows:—

"Yes," without qualification, was the reply of eight—The Philadelphia Orthopædic, Episcopal, Mercy of Pittsburg, Orange of New Jersey, Roosevelt of New York, Rhode Island of Providence, Buffalo, and Johns Hopkins.

"No," without qualification, was the answer of four—The German of Philadelphia, West Pennsylvania of Pittsburg, Boston City, Lakeside of Cleveland.

No answer was given by the Presbyterian of New York, Massachusetts General, University of Pennsylvania.

The Pennsylvania of Philadelphia says, "with a small number of rooms, as we have, the profits are small."

"Difficult to determine," writes the Presbyterian of Philadelphia.

St. Luke's of New York answers: "In wards, no; in private rooms, yes."

"Not satisfactorily determined," replies the New York Hospital.

The Boston City answers: "We do not consider paying patients profitable. The cost of a paying patient in a private room is not less than \$3.00 a day, and it is a losing game at that."

The Presbyterian of Chicago says: "Depends on how it is conducted."

The General Memorial of New York says: "Yes, for rooms renting above \$25.00 per week."

The conclusion to be drawn by hospital workers, supporters and endowers is a curiously mixed one. That there is glaring abuse of the private room system in some hospitals is asserted; that under the best circumstances it may be a failure is demonstrated. The question at least remains as to encouragement of the plan in hospitals to be built, or its extension in those already in use. Is it a proper use of money given for the benefit of the poor?

The Physician as Practitioner, Scientist, and Philosopher.—The ideal physician should possess a number of theoretic and practical qualifications such as an ordinary mortal but rarely combines. If a physician is a far-seeing individual, if he has the gift of quick and intelligent observation, together with the ability of associating ideas, if, in short, he is a man of shrewd common sense, it is not indispensably necessary for him to possess the highest possible erudition and scientific perfection to become an excellent clinician and perform most valuable services in the interest of humanity. But it certainly is a prerequisite to possess the philosophic qualifications for recognizing and diagnosing the cases he is called upon to treat and to take into proper consideration all the by-factors which may have a more or less determining influence upon the issue before him. A physician of that caliber, even without marching in the limelight of scientific supremacy, may be an ornament to his profession. On the other hand, the physician as a scientist pure and simple, may contribute the most learned dissertations on the special subject the exploration of which he has chosen as the task of his life; his scientific attainments may far exceed those of his humble confrere, the common-sense practitioner; and yet, for that matter there is no conceivable reason why he should be a greater or even as great a benefactor in the

realm of pathology. On the contrary, it is more than likely that he so binds himself up with that comparatively narrow circle of vision that pertains to his special branch of science that he is likely to approach everything from his own individual standpoint, look at everything through spectacles clouded by personal prejudice, try to explain matters of general import—so far as he attempts to explain them at all—from his own special point of view. He may, in fact, dote with the greatest possible application and fervor, with the zest and enthusiasm of the true scientist, upon minute details, but fail in the rudimentary principles of the common-sense practitioner. He lacks the power of initiative and force of creation. If nature has ever bestowed these priceless gifts upon him he is almost certain to lose them through one-sided study, through concentration upon one more or less theoretic subjects.

Champions of Retrogression.—Representatives of medical science, such as these, will but scantily contribute toward genuine progress in spite of the isolated discoveries which may, at few and distant intervals, light up their monotonous plodding like an unexpected shooting star in the dreary black of a dismal autumn night. When these scientists have once enshrouded themselves in their pet theories and notions, for the nursing of which they may have spent the best part of their lives, it is very difficult, and almost impossible for them to give the same up in favor of results attained by the genius of others, faulty though their own researches may have proved. In this respect they are veritable champions of retrogression; they obstinately cling to their own doctrines in which alone, they think, salvation lies ensconced, and thus produce a stagnation on the very field the cultivation of which they profess to have elected as their special domain. They thereby brand themselves as representatives of a doctrinary science—a science which has ceased to live, and which in reality is no longer a science from the moment that it is recognized to be false. Essentially great questions which have a true bearing upon the health of the individual, the health of the nation, the health of the human race, have never been asked by these representatives of science, but rather by those practical men who have no time for specifically scientific pursuits. From this point of view it would appear that the general practitioner who mixes with the people, who looks into the houses, into the beds, and into the stew-pans, who knows the world at large, and also the particular world in which he moves, who not only observes things, but also associates them with surrounding circumstances, can contribute far more food for the solution of philosophic problems than his brother who works with microscope and testing-tube. It is no cause for wonder, then, that the really great questions affecting the natural sciences have never been asked by professional scientists, nor is it cause for wonder that so many medical discoveries have been made—not by those who have devoted their lives to the confines within which the discoveries ranged, but by the unknown practical men who cannot boast the highest scientific education, and whose names are not always chronicled on the scroll of fame.

Scientific Drudgery.—There is, of course, no doubt that scientific drudgery is likewise a requisite adjunct to progress to a certain extent, but often there is little true thinking about it. It is drudgery pure and simple, and philosophy goes to the wall. And that is why the general practitioner who keeps his eyes open and his wits about him, who collects and sifts his impressions, and draws his practical conclusions, will usually recognize the seat and nature of an ailment in a far more satisfactory and reliable manner, and thereby render more good to his suffering brethren than his scientific confreres will do. Although scientific medicine so-called has made great strides in these latter days, especially in America, it is, if we want to be honest, sometimes nothing but a fad which presupposes and absorbs but little of the human mind—and the little minds of modern times are but too prone to follow slavishly a movement that requires but little perspicacity of mind to execute. It resembles the old story of the rat-charmer of Hamelin, whose alluring whistle the thoughtless youngsters of the village followed. Wholesale research in the laboratory is too commonly weak, but the practitioner possessed of good education and endowed with good powers of observation and association, who works by himself in the seclusion of his own study, and arrives at his own results and conclusions, represents a good type of individuality, and is strong. Paradoxical as it may sound, medical research as conducted nowadays is often nothing but hard labor, while the individual practitioner who exerts his intellectual faculties is the real philosopher.

"City Hall and Court House Sputistics" formed one of the most interesting and suggestive exhibits at the recent Tuberculosis Exposition in Baltimore. The following "sputistics" were collected by Dr. J. S. Fulton:

In eight walks around the City Hall on eight different days between the hours of 10 a.m. and 2 p.m., there were counted:

Separate deposits of sputum	2,013
Highest count, January 16, 1904	390
Lowest count, December 26, 1903 (bitter cold)	144
Average count	251.6

The filthiest spot was the Holliday street front; in the second degree disgusting, honors were divided between the southeast and the southwest corners.

In New York and some other cities it is reported that magistrates fine the spitters when brought before them, but in most cities there is no law against them, or no attempt at its execution. In Philadelphia *quis custodiet ipsos custodes?* Moreover, why build sanatoriums and permit the broadcast scattering of the germs for new infections?

The Atypical Child.—Under this title, Dr. Maximilian P. E. Groszmann read a paper Thursday night (Jan. 28), at the regular meeting of the German "Gesellig-wissenschaftlichen Verein," of New York. He said that he had suggested the use of the term "atypical" for a certain class of children, so as to distinguish them from the defectives, such as idiots, feeble-minded, blind, deaf-and-dumb, etc. While some provisions exist for the handling of the defective classes, little or nothing has been done for the atypical children. There may be distinguished three groups of these. The

first group is formed by what may be styled the "submerged classes," those who have for centuries been lagging behind the advance of civilization, and are really outside of it. They represent a primitive type of development. Their number is augmented by those children of originally normal conditions who, on account of some pathologic or other reason, have come to a stop in their natural progress. Especially the period of pubescence and adolescence is fraught with dangers; if children of this age are not properly handled, they may lose their bearings, and their rational development may be checked in the bud. While this first group is composed of children whose development may be said to be arrested, the other two groups represent merely a retarded or interrupted development. The second group consists of those where bodily causes, derangements of the digestive apparatus, difficulties of sense perception, etc., have thrown the child out of gear. Dr. Groszmann laid much stress upon the evil effects of adenoid vegetations. He said that the observable mental and moral difficulties can largely be cured by proper medical treatment, in addition to educational measures. There are also many children whose rate of mental growth is merely slow, but who really possesses much power. There is a third class, namely, that of children who are afflicted with disorders of the nervous system. Neurotic and neurasthenic conditions are very characteristic of modern life with its rush, excitement, and restlessness. There is overstimulation in school and home, under which so many children suffer; of the troubles of the adolescent girl whose nerves become shattered by overstrain in study at this critical period; of youthful hysteria; perverse tendencies; morbid conditions of fear; disturbances of sleep, appetite, and concentration; contrary activities; disturbances in the motor sphere, such as twitching, jerkings, habit tic, etc. Most of these children must be taken out of the ordinary school. For some it will suffice to establish special classes, such as are being instituted at present in some of our public schools. Others need an entire change of environment, proper hygienic conditions and exercise; a general tonic regimen, physical and mental, and a very rational method of instruction, including manual and physical training, and very much individualizing. Special schools will have to be established for their benefit, and a constant cooperation of physician and educator is necessary.

The Roman Catholic Church and Dissection.—In *The Messenger* for October, 1903, Dr. James J. Walsh corrects a popular error which has been inveterate during 600 years of modern history. It is asserted in practically all encyclopedia articles on the history of anatomy, that as a consequence of a Papal bull issued about 1300, forbidding the mutilation of the human body, all direct dissection, and consequently all opportunity for true progress in anatomy was hampered during several important centuries in the history of modern science. This presumed Papal prohibition is claimed to have precluded all possibility of the proper acquisition of anatomic knowledge until the beginning of the sixteenth century, when the golden age of modern anatomy set in. Notwithstanding almost universal concordance on the part of

writers of the history of anatomy in English, there are no good grounds for saying that the bull issued by Pope Boniface VIII was directed against the practice of human dissection. Moreover, this Papal document was not by any misunderstanding assumed by ecclesiastic authorities to forbid dissection. The practice of dissection can be traced at all the Italian universities during the two centuries in which the bull was supposed to have its deterrent effect; and these universities, it must be noted, were everywhere directly under the control of churchmen. During the fourteenth century the popes took up their residence in Avignon. This brought them into intimate relations with the university of Montpellier, and yet during their stay here the practice of dissection was not only not forbidden, but actually became one of the standard features of the university teaching, and special arrangements were made with the permission of ecclesiastic authorities by which the bodies of criminals were handed over to the medical department of the university to be treated as anatomic material. The story of the misunderstanding told by Dr. Walsh is convincing. It is strange that the real source of the historic error was a history written by churchmen. The object of the bull was to stop the practice of dismemberment and disemboweling which had arisen during the crusades.

Hospital Bookkeeping.—The Hospital Association of Philadelphia, through a special committee, renders a report upon hospital accounting which should receive the serious attention of all hospital superintendents and administrators. It recommends above all some uniform system whereby the statistics of expenses can be made of any use whatever in comparison with each other and for the benefit of those asked to contribute to support. For example, in determining the number of hospital days some only include actual days during which patients have been maintained—others count parts of days as full days, including dispensary patients, in their calculation. In determining cost of maintenance some deduct more, others less, from actual outlay. The Pennsylvania Hospital, the Presbyterian Hospital, the Germantown Hospital, the Methodist Episcopal, and the Jewish Hospitals include everything in cost of maintenance, except the cost and repair of permanent improvements. The University Hospital excludes medical and surgical supplies.

The committee believes that the actual cost of maintenance is the actual expenditure—but thinks it advisable to note, separately, the cost of creating and maintaining the hospital plant and the aggregate cost of maintaining the patients, without attempting to determine the total cost per day for each patient. It might be advisable to state the cost per day, per patient, for diet, medical supplies, light and heat, and nursing. But until there can be some agreement as to the basis of calculation one cannot expect statements of costs that may be correctly compared. The most of the hospitals reporting expressed the wish that there might be, at least, agreement in respect to the basis of calculation that correct statements of the cost of daily maintenance might be given to the public. It would hardly be pos-

sible to separate the cost of caring for private patients from the cost of caring for ward patients, and yet the average cost is of necessity greater in hospitals which care for private patients. Taking everything into account, it is the conclusion that the most satisfactory statement, both for the public and for the hospitals, would be something like the following:

- 1.—(a) Whole number of private patients treated.
- (b) Whole number of ward patients treated.
- (c) Number of full hospital days.
- (d) Number of patients remaining less than 24 hours.

These facts, fairly stated, would give a correct basis for calculating the actual service of the hospital.

2.—Cost of Plant Maintenance.

- (a) Administration and general wages.
 - (b) Improvements, furniture, and repairs.
 - (c) Interest, insurance, and taxes.
 - (d) Light and heat.
- Total cost of plant.

3.—Cost of Maintenance of Patients.

- (a) Medical and surgical supplies.
- (b) Nurses and attendants.
- (c) Food and clothing.
- (d) Emergency supplies.

Total cost of patients.

Courier or Companion Nurses.—The Hospital Association of Philadelphia brings up a new question as to the nursing profession. Because of the increasing demand for trained nurses as traveling companions, in care of the sick or convalescent patients, it recommends that the Association adopt or invite the preparation of an elementary textbook, possibly in the form of questions and answers, that will be useful to nurses and others needing information as to hotel and traveling rules and customs at home and abroad. It also suggests the desirability of acquiring a knowledge of French, possibly as a postgraduate course, by nurses contemplating acting as courier companions in foreign travel; the preparation for this service should be entirely elective or voluntary on the part of each individual nurse. The hospital records of graduate nurses should include a reference to the foreign languages they speak, if any, and attention should be directed to the fact that some of the hospitals, when they have desirable applicants and no vacancies in their training schools, endeavor to secure for such applicants temporary positions as companions, where no trained nursing is required, to occupy their time until an opportunity occurs to enter the training school.

Doctors and their Incomes in the United States.—There are about 200,000 doctors in the United States, or about 1 for every 350 people. It has been approximately estimated that the average yearly income of these men is \$750, or that the public in the country pays \$150,000,000 annually for medical attendance, omitting entirely the money spent for patent medicines which brings millions of dollars to manufacturers, or the amounts spent for doctors' prescriptions, or paid to quacks and commercial doctors. The preparation for the practice of medicine that gives a man a good standing in the profession means an expense of, liberally speaking, \$4,000 for 4 years in a reputable medical school, \$1,000 for general expenses during 2 years' hospital service, and, perhaps, another \$1,000 for setting up in practice. A year or two in Europe is also a help.—[*Leslie's Monthly*.]

AMERICAN NEWS AND NOTES.

GENERAL.

Sleeping Sickness.—According to newspaper accounts, a young girl of Centralia, Ill., has died from sleeping sickness. This is considered interesting in connection with the statement that Dr. Muhlberg, bacteriologist of the medical department of the University in Cincinnati, has found the germ which causes sleeping sickness in rats. It is thus believed that the disease may be conveyed by ships to ports of any part of the world.

Eddyite Treatment Failed to Cure Even a Cow.—The Denver *Republican* of January 14 says: "It is not expected that Mrs. Anna Tweedy will practise eddyite methods of healing upon dumb animals in the future. The State Humane Society, through Assistant Secretary Oliver E. Tuft, recently prosecuted her in Justice Byrne's court on the charge of cruelty to animals, alleging that she tried to heal the broken hip of her cow by absent treatment. The court imposed a fine of \$100 and costs, but owing to the fact that Mrs. Tweedy is not wealthy and is a cripple, the fine was remitted."

Miscellaneous.—THE DAILY MEDICAL is the title of a daily publication, the first number of which appeared February 8, 1904. Its editorial columns set forth that it is to be published daily, Sundays excepted, and is to be devoted to medical literature. It will combat the various evils which beset the medical profession of today, will advocate a united profession, and will urge legislation on all appropriate medical subjects. The first issue at hand is sprightly, interesting, and indicates that the journal will be worthy of success. The editor is Dr. M. W. Curran, and the *Daily Medical* will be published in New York. —SOUTHERN MEDICINE AND SURGERY is the title of a new monthly journal published in Chattanooga, Tenn. The first issue appeared in January and it contains some valuable reading matter.—It is reported that Dr. Nicholas Senn has gone to Japan, to assume charge of the surgical corps of the Japanese army.

To Fight Mosquitos.—The Monterey Board of Health is now distributing thousands of small earthenware bowls containing a mixture of sulfur and saltpeter and suspended by wires so as to be easily let down into a well. The object is to thoroughly disinfect all wells, and every householder is cautioned to ignite the sulfur and lower the bowl into the well by a cord, so that all portions may be cleansed of whatever mosquitos may live there. The expense of this is borne by the Board of Health department, and thus early means are taken to prevent a recurrence of yellow fever this year. No effort is being spared by the officials to kill every mosquito, and to this end the entire force of the Board of Health is working in harmony with the civil authorities. Various stagnant pools in different parts of town are being filled, disinfection is going on all the time, and everything possible is being done to avert the fever.

Filthy Money.—A bill has been introduced in Congress which provides that the banks shall forward to the treasury, for redemption and reissue, all notes coming into their possession, whenever the amount on hand reaches \$1,000. The explicit purpose of the bill is to do away with filthy bills which are constantly in circulation and thus diminish the dangers of infection from this source, to say nothing of the esthetic side of the case. The *Philadelphia Ledger*, commenting on this editorially, says in part: "A million or two of bacteria are carried in the pocket of nearly every one who possesses an old dollar bill, but a man who refuses a note because it is filthy is regarded as too eccentric for the transaction of business. We are all so eager to seize money in whatever form it appears that we do not wait to disinfect it. We boil suspected water, but we cannot boil our money. Possibly, long contact with infected money has made some of us immune; but even if there be no peril in the rags that are 'legal tender,' clean or unclean, the public is entitled to have decent bills. In some portions of the country a respectable looking bank note is a curiosity."

EASTERN STATES.

Typhoid Epidemic Caused by Flies.—Information from New Haven, under date of February 3, says: To flies which carried contagion is ascribed the epidemic of typhoid fever which afflicted 21 patients, causing 7 deaths, at the New Haven county jail. A report of Dr. H. E. Smith, of the Yale Medical School, and Dr. Edward Mahl, of Hartford, who were appointed to investigate the cause of the epidemic, says: "The occurrence of several cases of typhoid fever in houses in Hudson street, near the jail, which must have infected the premises, the abundance of flies, the open communication between the jail kitchen and the adjoining yards through the windows, all suggest the probability that the infection was brought into jail by flies. From the nature of the cases such transmission cannot be proved, but it is rendered probable by the conditions known to exist and the consideration that these insects have been a potent cause for the dissemination of typhoid fever during the warm weather in military camps."

NEW YORK.

State Charity Wards in New York.—The thirty-seventh annual report of the State Board of Charities, just sent to the Legislature, shows that there are 61,935 persons in the several charitable institutions. In addition temporary relief was given to 29,773 persons. The expenditures for 1903 amounted to \$1,863,218.83, and for this year \$2,334,325 is asked.

Reduced Deathrate in New York City.—The State Department of Health, in its bulletin of vital statistics, states that there were 127,100 deaths in 1903 in this State, a mortality of 16.7 per 1,000 population. The bulletin states: "The infant mortality exceeded that of 1902 by 1,500, but was 4,000 less than the average. The 22,000 deaths at the age of 70 and over, constitute the same percentage of the entire mortality as in 1902—17%. Smallpox caused 41 deaths, all but 16 occurring in and about Rochester. There were 10,250 deaths from pneumonia and 7,960 from Bright's disease. The acute respiratory mortality was about the average. The grip is estimated to have caused 8,000 deaths, and its annual recurrence is apparent during the closing weeks of the year."

Insane in New York State.—A large increase in the number of insane persons who have gone for treatment to the various State hospitals and licensed private asylums is noted in the annual report of the State Charities Aid Association, which has just been issued. For the past 6 years the total increase of the insane in both public and private institutions has averaged 708, but the increase up to October 1, 1903, was 941 over the previous year. The increase in the State hospitals, not including the 2 asylums for the criminal insane, was 918; as against 663, the average of the past 6 years. There are at present nearly 26,000 patients in the insane asylums of the State. It is proposed to erect 2 reception hospitals in Greater New York for preventive treatment in incipient stages for those afflicted with mental disease. These would do away with the concealment and neglect so usual at present, and would also serve as centers from which knowledge could be disseminated to the medical schools and throughout the medical profession. With such a hospital, it is declared, the city could do away with a psychopathic ward in connection with the new Bellevue Hospital.

Guarding the Water Supply in New York State.—In a recent message to the Legislature, the Governor of New York, concerning typhoid and other infectious diseases, says: "A complete record of the sources of public water supplies and the possible conditions which may produce epidemics of typhoid fever or other infectious diseases should be secured by the Health Commissioner, and I recommend that an appropriation be granted by the Legislature for this purpose." Commenting on this an exchange says: "According to a report from the State Commissioner of Health, there were nearly 25,000 cases of typhoid fever, with a mortality of 1,635 cases, in New York State during 1903. If we take each life sacrificed to the fever to represent \$5,000, as is commonly calculated, there was lost last year, through the deaths alone, \$8,175,000. Assuming the expense of nursing the 25,000 cases at the low figure of \$50 apiece, the cost of the sickness was \$1,250,000. If one-fifth of those who were sick were wage earners, receiving wages which averaged \$1.50 per day, and each patient was incapacitated for work about 6 weeks, the total loss of earnings would probably exceed \$270,000. Bringing these several items together, the grand total of the cost of typhoid fever to the citizens of New York State is found to have been over \$9,695,000."

Crowds of Immigrants and Their Diseases.—In an address before the Universalists' Club, New York City, Mr. Frederick H. Page is quoted as stating that 2 whole regiments of immigrants leave European ports every day in the year for New York. During 1 day on which he visited Ellis Island the officials handled 2,400 immigrants from Bremen and 200 from Liverpool. As many as 6,000 have been handled in a single day, while in 1 day, April 9 last, 12,600 steerage passengers arrived at Ellis Island. These immigrants are examined to determine if they are affected by any contagious disease. During the year 1902, 748 of them were deported because of being afflicted with trachoma. Beginning in April, 1903, a fine of \$100 was laid on steamship companies for every case found, which could have been detected before the ship sailed. Vigilance at Ellis Island has caused such diseased immigrants to enter the United States via Montreal and at other places on the Canadian border. But such vigilance has been shown by the United States inspectors there that the astonishing number of 5,158 diseased and otherwise objectionable immigrants have been denied entrance on the Canadian frontier. They are now coming in from Mexico, where our frontier is not so well guarded. Some 857,000 steerage aliens entered the United States in the year ended June 30, 1903, and 682,000 of them entered via Ellis Island, 63,000 through Boston, 56,000 through Baltimore, 28,000 through Philadelphia, and scattering thousands through the smaller gateways. This is not only an increase of 208,000, or 32% on the total immigration of the previous year, but it is the greatest year of immigration ever known.

PHILADELPHIA, PENNSYLVANIA, ETC.

International Course on Tuberculosis.—The next lecture in the International Course on Tuberculosis, under the auspices of the Henry Phipps Institute, will be given by Dr. Herman M. Biggs, chief of the Department of Health in New York, on Monday evening, February 15, at Witherspoon Hall, the subject being the "Administrative Control of Tuberculosis."

Decrease in Smallpox.—Smallpox showed a decided decrease in the number of new cases reported to the Bureau of Health for last week, as compared with the previous week or any week in the last 2 months. There were 54 cases and 16 deaths from the disease, compared with 65 cases and 17 deaths for the previous week. Typhoid fever also showed a marked falling off, 88 cases and 13 deaths being reported, as against 126 cases and 10 deaths for the preceding week.

American Society of Tropical Medicine.—Dr. James Carroll, who is now stationed in Washington, as instructor in bacteriology in the United States Army Medical School, delivered an address upon the etiology of yellow fever, on Saturday evening, January 9, in the auditorium of Houston Hall, Philadelphia. Dr. Carroll is a member of the celebrated commission appointed by the Surgeon-General to investigate yellow fever in Cuba, and is a wellknown expert on tropical diseases. He came upon the invitation of the American Society of Tropical Medicine. Dr. Carroll reviewed the early researches upon the etiology of the disease, giving special consideration to the work of Freire, Sanarelli, and Finlay, then the work of the commission, whose researches have now become world wide, and proving that yellow fever is propagated by the bites of the mosquito known as *Stegomyia fasciata*. It is only the female mosquito that bites, therefore, only the female mosquito that becomes infected. The mosquito is able to impart the disease only after 12 days have elapsed since its own infection, and may retain the ability to infect after many months, providing it does not meet with destruction in the meantime. A description of the experiments made to show the infectiousness of fomites, seemed to exclude all possibility of yellow fever being transmitted directly. Confirmation of all of the work of the United States commission has been given by the more recently appointed French commission. For information regarding the society, apply to the secretary, Dr. Joseph McFarland.

SOUTHERN STATES.

"Maryland Medical Journal."—Our esteemed contemporary, the *Maryland Medical Journal*, through the recent conflagration in Baltimore, has lost the entire issue for the month of February. This is especially regrettable on account of its containing a number of valuable papers and an exceedingly rare and valuable report concerning the recent Tuberculosis Congress held in Baltimore. The regrettable occurrence is a distinct loss to the profession.

Care of the Insane in Maryland.—News from Annapolis under date of February 3, says: "A notable reform is attempted by the bill introduced relating to the care of the insane in the State. Its provisions require the State to assume absolute charge of all insane persons who are residents of the State at present, or who may hereafter be adjudged insane, and that they shall be confined and treated in institutions under the management of the State. In furtherance of this purpose, provision is made for the transference, as soon as practicable after the passage of the bill, of all insane persons confined in institutions under the control of the different counties. In most of the counties of the State there are insane persons in almshouses, jails, and other such places, where the facilities for handling them are entirely inadequate and improper."

WESTERN STATES.

No Funds to Manufacture Antitoxin.—The University of Illinois, through President Draper, has refused to manufacture antitoxin at the University laboratory, because of lack of funds to start the work. It was stated that, although the University was empowered to manufacture antitoxin and vaccine lymph, it would be impossible to do so at this time, as no money was available for the purpose.

Vitality of Diphtheria Germ.—That diphtheria may live in packed clothing almost indefinitely is shown by an incident which occurred in an Ohio village. A child died of diphtheria and its mother packed its dresses and toys in a chest. The mother died 15 years afterward, and her daughter and granddaughter, who opened and handled the contents of the chest, were duly taken ill of diphtheria, although there had recently been no cases in the village.

Free Nurses Care for Thousands in Chicago during 1903.—Patients numbering 7,252 were cared for 46,058 times last year by members of the Visiting Nurses' Association, who expended \$23,321. This report was made recently at the annual meeting of the charitable organization in the Unity Building. The association has 19 nurses, and no pay is received from persons attended. Contributions of the year were \$25,768, and 408 cases of tuberculosis and 307 cases of typhoid fever were treated in 1903.

FOREIGN NEWS AND NOTES

GENERAL.

The Heathen Chinese.—Dissection has no place in the Chinese study of anatomy. The Chinese look upon the skull and the pelvis each as one bone. They think that the small intestine communicates with the cavity of the heart, while the colon terminates in the lungs; that the liver is the habitat of the soul; that the gallbladder is the receptacle of courage; that in its ultimate structure the body is composed of fire, water, earth, wood, and metal. Truly, this is fearful and wonderful.

To Purify the Air.—M. Desgrez, in the *Bulletin of the French Physical Society* (No. 185), describes a new apparatus for maintaining a supply of pure breathable air in a small closed space. It consists of a distributor which, by the action of clockwork, drops sodium peroxid into water at regular intervals, a cubical steel box, and a ventilating fan. The sodium peroxid is decomposed by the water with liberation of oxygen, absorption of carbon dioxide, and destruction of the other toxic products of respiration. A refrigerator is also supplied to counteract the heating effects of the chemic reactions. The complete apparatus weighs about 26 pounds.

New Method for Sterilizing Water.—Professor Paterno, an Italian, has suggested a process for the purification of drinking water, which constitutes a great step forward in the study of this important problem, says the *Tribuna*, Rome. From numerous and extensive experiments made by this author it appears that by adding to impure water, even that containing pathogenic microbes, an extremely small quantity of silver chlorid, there is accomplished the complete disinfection of the water. For this purpose 2 mg., or at most $2\frac{1}{2}$ mg., of the chlorid, insufficient to absolutely sterilize a liter of water and to eliminate every danger of infection. The sterilization is completed in a few minutes—10 at the most—and no apparatus is necessary beyond a small vial with a solution of silver chlorid.

OBITUARIES.

Joseph B. Roe, at his home in Woodbury, N. J., February 5, aged 68. He was graduated from Princeton University in 1858, and from the medical department of the University of Pennsylvania in 1861. He served as a surgeon in the Federal Army during the Civil war for four years. He served in both branches of the State Legislature of New Jersey, and was at one time postmaster at Woodbury.

Henry Buehler Buehler, at his home in Harrisburg, February 1, aged 69. He was a graduate of the Jefferson Medical College. He served as surgeon in the Federal Army during the Civil war, and for his bravery was made a member of the Loyal Legion of Philadelphia. Of late years Dr. Buehler had devoted most of his attention to insurance.

W. H. Gale, a prominent resident of Somerset county, Md., at his home February 3, aged 74. He was formerly in active practice, but retired some twenty years ago. At one time he was register of wills of Somerset county. He also served in the State Legislature and was well known in his community.

John B. Murphy, at his home in Brockville, Ont., January 17, aged 54. He was a graduate of the College of Physicians and Surgeons of Ontario, Toronto, in 1876. He was medical superintendent of the Hospital for the Insane at Brockville, and widely esteemed for his knowledge and ability.

Oliver Chase Wiggin, in Jacksonville, Fla., February 3, aged 63. He was a graduate of the medical department of Harvard University in 1866, and at one time president of the Rhode Island Medical Society, and president and secretary of the Providence Medical Association.

George Thompson, at his home in New York, February 2, aged 87. He was born in Belfast and came to this country in his youth, graduated in medicine and had practised in New York City more than forty years. He retired from practice some fifteen years ago.

D. F. Murphy, at his home in Woburn, Mass., January 31, aged 44. He was a graduate of Harvard Medical College in 1887, a member of the Massachusetts State Medical Society and of the Eastern Middlesex District Medical Society.

W. W. Firestone, at his home in Wooster, O., January 25, aged 61. He was graduated from the Charity Hospital Medical College, Cleveland, O., in 1865 and a member of the American Medical Association.

Aaron S. Van Buskirk, at his home in Fort Wayne, following an operation for gallstones, January 25, aged 56. He was a graduate of the Medical College of Ohio, Cincinnati, in 1876.

Charles J. Warner, at his home in Congress, Ohio, from cancer of the stomach, January 23, aged 68. He was a graduate of the Cleveland Medical School in 1862.

W. S. Charlton, at his home in Philadelphia, February 2, aged 46. He was a graduate of the University of Pennsylvania in 1883.

C. B. Naudain, at his home in Wilmington, Del., February 2, aged 67. Death was supposed to be due to paralysis of the heart.

CLINICAL NOTES AND CORRESPONDENCE

[Communications are invited for this Department. The Editor is not responsible for the views advanced by any contributor.]

SCHOOL HYGIENE.

To the Editor of American Medicine:—In Dr. Smith's article on "School Hygiene," in your issue of November 7, there is one statement so at variance with the general good sense of the article that I feel that I must take issue with it, since were it to go unprotested it might do harm.

In speaking of the duties of a school janitor, she includes, very naturally, the supervision of the heating of the school building, which is unquestionably an all-important matter, for the temperature in which our children live and work has much to do with their health and welfare. When she says, however, "he should keep the temperature constant at from 76° F. to 80° F. for young children, and from 72° F. to 78° F. for older children, according to the climate," I feel that she is giving advice which certainly would be harmful in its results if generally followed. Unquestionably the average American is too used to rooms excessively overheated, and that is just the reason why he should begin to learn at school in early childhood what proper room temperature should be. I am sure that the pediatricists of this country will agree with me when I say that for no child in health is a temperature of a workroom from 76° to 80° proper, or even tolerable. Not only are these degrees too high, but the lower degrees of 72° to 78° far too great.

It has been very generally settled by hygienists, that the ideal room temperature is 68° F., which may be varied, however, to run from 65° to 70°. When you pass 70°, you begin to make heat harmful.

While this may seem a very small point to call forth a letter, I do not think that any one whose work causes him to pay careful and especial attention to hygiene would think so, and I trust that the Doctor herself in thinking over the matter, will agree to the correctness of my criticism and make her teachings in future more conformable to the standards that experience has set in this direction.

Asheville, N. C.

CHARLES L. MINOR, M.D.

I hope the foregoing letter may succeed in stirring up a general discussion and investigation of this most important question now under dispute; if so, the verdict of the majority will be accepted as the standard temperature for schoolrooms and I shall have done no harm.

I still believe that a "constant temperature at from 76° F. to 80° F. for young children and from 72° F. to 78° F. for older children, according to the climate," is correct for schoolrooms. The old fallacy of the "hardening process for children" is becoming quite universally discredited. I do, however, quite concur with you as regards "the ideal room-temperature" for healthy adults being from 65° F. to 70° F.; but how different are the conditions in these two instances! On the one hand, we have the fully developed adult, who only needs sufficient heat to carry on the ordinary processes of life, those incident to tissue waste and repair—the individual has become adjusted to his environment and he no longer needs the extra heat, unless he be engaged in some sedentary occupation requiring excessive mental labor and fatigue, in which case he, too, will find, providing the air is pure, the additional heat of from 2° F. to 4° F. above "the ideal room-temperature" almost necessary to his comfort and well-being while so occupied; even the older children engaged in some active occupation will find such a room temperature as you mention quite correct. But, on the other hand, children have the same conditions of life to meet as to tissue change and repair as does the adult, plus the strain incident to the developmental stages of life, hence they need more heat.

Let us stop for a moment to consider the lives led by average schoolchildren. They eat a hasty breakfast and hurry away to school. Those who are ahead of time engage in active play, while those who are late run part or the whole of the distance that they may be on time for "the bell." At any rate, when school opens the children are overheated, owing to the active exercise taken, the wearing of rubber raincoats or other

causes, and consequently, the blood is determined to the surface of their bodies and the process of digestion is retarded. Now let them sit for a while in a room with a temperature at from 65° F. to 70° F., they are very likely to "feel cold," with the result that the blood continues to be determined to the surface of their bodies and digestion, at best, to be carried on in a very imperfect way. Again, in the colder climates, children may become so chilled on their journey to the school that, if the room temperature be only from 65° F. to 70° F., their reaction to the warmth of the room may be so slow that they will remain uncomfortably cold for the rest of the school session. It cannot be otherwise, for they must sit quietly and study as diligently as they can be made to do—at any cost the school order must be maintained!

When you think how occupied their little brains are during school hours, with work that taxes their mental capacity to the point of bodily fatigue, and even to the point of exhaustion; how they must sit quietly at study and recitation, what a common experience it is for most brain-workers and others who are engaged in sedentary occupations to have cold feet; how cold feet are caused by an unequal circulation, which in turn tends to impair digestion, and thus cause other abnormalities, from which schoolchildren should be exempt; how many schoolchildren there are who arrive at school with damp clothing and, very many times, with wet feet, I think you will agree with me that it is not only important to have free air, but also to have a higher room-temperature to meet the manifold needs of the average schoolchildren than is essential to the requirements of the adult. Just here I might add, that in this climate, Tacoma, Wash., 66° F. to 68° F. would be the minimum, and from 70° F. to 74° F. would be the maximum temperature required.

I do not think, when the pupils are sitting during school time, there is so much danger to be feared from a constant temperature of 70° F. to 80° F. as from an irregular one, although, of course, we all recognize the evils of excessive temperature in the heating of rooms. But, also, we must not forget that a temperature that would be excessive for the adult may not be excessive for children; and that the temperature of the room for children at play or at work need not be as high as for children sitting quietly at study.

The great advantage I claim for the system of a medical supervision of schools, which I am advocating, will be that all matters pertaining to "school hygiene, the development of children, and preventive medicine," will receive careful consideration from those competent to understand the questions involved from a much more practical and comprehensive point of view than otherwise is possible.

It is only through such investigations, made after such a plan, that an objection like the one made by Dr. Minor can be satisfactorily studied and settled for the different parts of the country.

Tacoma, Wash.

ALICE M. SMITH.

GLUTEN FOODS.

BY

ARTHUR H. HOYT, M.D.,

of New York City.

To the Editor of *American Medicine*:—In your issue of November 21, is an article headed "The Diabetic Flour Swindle," in which you quote from the *New Hampshire Sanitary Bulletin*, the analyses made by its chemist of the various gluten flours advertised in this country. I am writing you from the standpoint of a manufacturer producing a flour that is being put on the market. I desire to criticize your article, not the part from the *Sanitary Bulletin*, which you have quoted, but more especially the editorial comment following: "And now comes the revelation, which we have in these columns prophesied. That there is no pure gluten flour to be had. That most of that so advertised is nothing more nor less than common wheat flour." We agree with you in stating that *much* so advertised, tests about the same as common wheat flour, but if you will look at the column of proteids in the table epitomizing

the work, you will notice No. 3, the analysis of ordinary spring wheat flour, which you undoubtedly mean when you say common wheat flour. The analysis of this practically shows a protein content of 11.38%. You will further note in the same column, 6 others that show a content of over 30%. Three in that same list are not called gluten flour, nor are they supposed to be advertised as diabetic foods. Some show a content of over 75% proteids, which is certainly very high, approaching nearly the highest we have ever obtained, which was 83% protein. There is certainly a great variation in the qualities of gluten flours mentioned in that table. But it seems to me the question for consideration, if you desire to give advice to the medical profession, is that it would pay to try to arrive at some correct standard.

There are manufacturers who are trying to produce an honest article, and the medical profession should arrive at some standard of purity, so that figures given in tables like this shall have some meaning. If you stop to consider that in the making of bread, yeast is used, and that the soil required for yeast is made up of carbohydrates, you will understand that it is quite necessary that there should be a certain amount of carbohydrates in gluten flour, otherwise the bread could not rise, that the yeast breaks up the carbohydrates into carbon dioxide and alcohol. When the gases have expanded, and the bread becomes baked or fixed in a loaf, the result should be pure gluten bread.

It is possible to take gluten, as it comes from the process of making wheat starch, and by further processes make it considerably purer. In fact, we are producing flour that is testing as high as 83% protein, but it has long since been found that such flour is impractical as a food, not because of its actual food value, but because it cannot be made palatable. Different batches of flour in our process produce gluten which varies somewhat, and which cannot be entirely controlled. Occasionally gluten is produced that would test as high as 53% protein, and almost invariably there is trouble in making bread from it. But regularly testing from 43% to 50%, makes possible good, palatable bread, and diabetics have had perfect results from its use. The small amount of starch represented can be oxidized if there is any vitality and no organ be over-taxed.

MAXIMUM AND MINIMUM FEES.

BY

JOHN MARSHALL GEST, Esq.,

of Philadelphia.

To the Editor of *American Medicine*:—In *American Medicine*, January 23, 1904, on page 127, appears a note entitled "Physician May Charge Maximum or Minimum Fees," containing the opinion of Judge Ashman, of the Orphans' Court, which is so inaccurate as to require correction. The case was not a contest between a Philadelphia physician and a "belligerent patient," but an attempt on the part of an Atlantic City doctor to charge a fee (adjudged by the Orphans' Court to be excessive) against the estate of his deceased patient.

The opinion of Judge Ashman on the question of "maximum and minimum" fees was stated by him to be merely his personal view, which was expressly repudiated by the other judges of the court in an opinion by Judge Penrose, which is given below.

In this case all the judges concurred in dismissing the claim of the physician for a larger compensation than that allowed by the auditing judge, and Judge Ashman said: "The charges of the several physicians and surgeons who attended the decedent in her comparatively brief illness exceeded \$1,500. A review of the testimony satisfies us that the award to the exceptant was made after careful deliberation, and is entirely just."

Penrose, J., concurring, January 7, 1904: That a physician may adopt a minimum rate of charge for his professional services to the poor, and a maximum rate, regulated only by his mere volition or fancy, in dealing with the rich, admits, of course, of no possible doubt, either as an abstract question of personal liberty or as a matter of bookkeeping; and if the maximum should be in excess of real value, the only conse-

quence would be that patients who survive the first employment will probably, after receiving their bills, not repeat it.

But when, in a court of justice, and especially in the court established to protect those no longer able to protect themselves, he demands payment for services rendered to a decedent, he is required to show not only that the services were rendered, but their value; and in the absence of proof of a special contract, or, at least, of knowledge on the part of the patient of the rates which he has thus seen fit to adopt, such rates will not avail him in the least degree. Here the distinction of rich and poor has no existence; the sole question is the intrinsic, commercial value of the services for which compensation is asked, and leniency on the part of the claimant in his dealings with the humble cannot be urged as a reason for demanding overpayment from the more wealthy. Manifestly his unsupported estimate of value will not be accepted as conclusive, while the fact, as in the present instance, that his "maximum" charge is only asserted as against rich, or supposedly rich, strangers temporarily sojourning at "first-class hotels or high-priced boarding-houses," while the so-called "minimum" is not only what equally reputable physicians charge in their general practice, but his own rate, to rich and poor alike, in his practice among resident patients, furnishes the strongest evidence that his maximum is unreasonable and excessive.

These, at least, are the views of the majority of the judges before whom the exceptions were argued, but as all were of opinion that the exceptions should be dismissed, the methods of reaching that conclusion are only important as affecting cases which may hereafter arise.

CASE OF PROTRACTED HIGH TEMPERATURE.

BY

L. H. MAYER, M.D.,
of Johnstown, Pa.

Protracted high temperature is so rare a condition that I consider the following case noteworthy:

The patient, M. B., was born September 17, 1902. There was nothing unusual about the delivery, and the child was plump and well developed. The mother states that from birth the baby seemed to be unusually warm. However this may be, when the baby was 3 months old, I was called to attend it in an illness which appeared to be due to pneumonia. The temperature was 104° F. and pulse 120, and she had all the other signs of a serious illness. There was gradual subsidence of pulmonary symptoms, but the temperature remained singularly high, and the pulse continued fast. After 3 weeks of vain attempts at reducing the temperature by means of the application of ice and sponging, and by the administration of digitalis or quinin, I reluctantly came to the conclusion that this treatment was of no avail. The child's general condition, however, was fairly good. It had lost very little, if any, in weight, was intelligent, but fretful, and slept well. A urinary test at this time revealed the presence of albumin, and I thought I had at last found a cause for the remarkable continuance of fever. Subsequent tests, however, proved the condition was transient. All treatment was now suspended, except that a digestive was used, as there seemed to be some tendency to stomach derangement. The baby up to this time was breast-fed; the mother was healthy. There is nothing in the parental history to indicate a hereditary taint, but 4 children died in early infancy. One child, however, is living, aged 13.

My little patient continued in her usual health until June 1, at which time an illness began similar to the one detailed, with the difference, however, of a much higher range of temperature. Treatment was practically without result. The mother has had in use probably a dozen thermometers, always getting another upon breaking one, and since the beginning of the first illness the temperature has never been under 101° F., and has usually been in the neighborhood of 102° F. During the second illness, when the child was about 8 months old, 4 teeth made their appearance in proper sequence. The child all this time had shown some tendency to gastric derangement, and because of a failure to gain in weight, artificial feeding was added to the mother's nursing. For some time now one or other of the iodine medicines was being used, and though without result, the child is still taking a prescription containing iodine in some form.

Recently I chanced to meet the father and asked him how the child was doing. He replied, "Oh, first rate!" When asked what the temperature for that morning was, he replied, "104°!"

The child has attained sufficient length and is apparently well nourished, but the skin has a peculiar unhealthy appearance. The tongue and teeth are apparently healthy. The eyes are large and bright, and all the senses seem active. The child plays and is quite intelligent. Examination of the back and all the joints reveals nothing, and she supports herself, but does not make an effort to walk. The mother says her temperature this morning was 102.4° F., and any thermometer you wish to use will now register not less than 102° F.

I have failed to find anything in literature resembling this case. In "Anomalies and Curiosities of Medicine," by Gould

and Pyle, reference is made to instances of very high temperature, but there is no mention of a case of protracted high temperature.

I think it is fair to assume that this is an instance of individual peculiarity, and this peculiarity may be stated to be due to a perversion of the heat center in the brain.

I have recently been using bromids and iodids, but I have little hope of improvement resulting from medication. I am forced to the unfavorable conclusion that the patient, though now intelligent, if she lives, will develop a brain lesion that will eventually deprive her of all intelligence.

EFFECTS OF AN OVERDOSE OF BROMOFORM.

BY

CHARLES E. FILBERT, A.B., M.D.,
of Atlantic City, N. J.

The case of "Poisoning Due to the Chemic Decomposition of Bromoform," cited by A. G. E. from A. L. Oberdorfer, and published in *American Medicine* of January 2, 1904, p. 39, calls to my mind a case I saw in the spring of 1903.

The cases are not precisely analogous, but have certain characteristics of similarity, and teach the same lesson, namely, a danger in the administration of a combination which has won its way, and rightly, into the profession as a valuable anti-pertussic remedy.

Whether the danger lies in the chemic decomposition of the preparation, or in its indiscriminate or injudicious administration, the occasional occurrence of cases like these sounds a note of warning:

The boy was about 4½ years old, and was suffering from pertussis previous to the family's leaving for the shore. His mother showed me a box labeled on the outside "Take as directed," Dr. ——. On the inside of the lid were the following directions to the apothecary: "Partially fill capsules with pulv. sacch., and drop 10 drops of bromoform on sugar. Then put this capsule into another larger one to prevent evaporation of the medicine."

The mother said she had given the child a capsule late in the afternoon, and as he did not seem bright, just before supper she repeated the dose. A short time after giving the second capsule he became very drowsy and was kept awake with the greatest difficulty.

On examination I found him pale, slightly cyanosed, with a rapid, feeble pulse. On being shaken and spoken to he would open his eyes, but immediately lapse into unconsciousness.

Strychnin sulfate 1 mg. (⅓ gr.) hypodermically, improved the pulse and aroused him somewhat. In the course of an hour he was himself again.

The case is interesting from the standpoint of overdosage and the lack of specific directions. "Take as directed" may mean every 4 hours 1 day and every 2 hours the next, depending entirely upon the memory of the nurse or mother.

TO PREVENT PNEUMONIA.

BY

BEVERLY ROBINSON, M.D.,
of New York City.

To the Editor of *American Medicine*:—May I add one do to some of the don'ts relating to pneumonia published in *American Medicine*, January 23, 1904, p. 124. The experimental researches of Welch show that *Micrococcus lanceolatus*, the admitted cause of croupous pneumonia, is a pathologic organism, but little tenacious of life, and whose loss of virulence is frequent and apt to occur rapidly. Is there not in this important fact a very substantial reason why we should endeavor to employ antiseptic inhalations early in the treatment of pneumonia, before lung consolidation has taken place, and while we may yet hope legitimately that the antiseptic vapor may reach every portion of the affected pulmonary area?

Families Decreasing in Size.—According to the Statistical Atlas of the United States, newly issued by the Census Office, the average number of persons to a family has declined from 5.6 in 1850 to 4.7 in 1900. In 1870 the average was a trifle above 5.

ORIGINAL ARTICLES

A CASE OF GUNSHOT WOUND OF THE BRAIN.¹

BY

JOHN A. WYETH, M.D., LL.D.,

of New York City.

A. T. I., aged 23, came under my care at the Polyclinic Hospital, August 11, 1903, through the courtesy of Dr. W. H. Sampson, of Mount Hope, W. Va.

In the February preceding, a spheric bullet fired from a 32-caliber pistol, had entered the cranium through the frontal bone, at a point about an inch to the right of the median line of the skull, and about the same distance from the junction of the interparietal with the frontoparietal suture. There was no wound of exit. The hemorrhage which was slight ceased spontaneously. He was carried to an emergency hospital in a neighboring mining town, but no effort was made to locate or remove the missile. He remained here about 2 months and was then removed to his home, being confined to bed the greater part of the time. While he was at no time entirely unconscious, he suffered evident impairment of the mind from the date of the receipt of the injury. He was at times delirious and while there was no paralysis of the sphincters the contents of the bladder and bowels were often passed without the consciousness of the patient. The track of the wound became infected soon after the accident and the opening was gradually plugged with a protrusion of granulation tissue through which a small quantity of pus discharged. There were at no time any symptoms of injury to the motor convolutions of the brain, nor to the special senses.

When, 5 months after the accident, I examined this patient, I found the local conditions as just described. The patient's intelligence was seriously impaired. He talked incoherently, was restless, and in order to prevent him from leaving his bed and wandering about the ward he had to be kept under constant watch.

Careful radiographs by Dr. J. A. Robertson, of New York, were taken from both sides of the skull, as well as from the front and back. That from the patient's right side showed the foreign body very distinctly. The picture from the left side was less distinct, while that from in front showed it, though dimly. The radiograph taken from the occipital region gave no trace of the missile.

As soon as the patient could be properly prepared for operation I cleared up the wound of entrance, and when a Nélaton porcelain-tipped probe was carefully introduced it practically found its way along a slightly tortuous route until at a depth of about 3 inches it came in contact with a hard substance resting upon the orbital plate of the frontal bone. Withdrawing the probe, I carried my finger in the direction which it had taken along the suppurating track to the base of the skull where I felt the bullet, and then by guiding a delicate forceps along the palmar aspect of the finger, the foreign body was extracted. In order to secure proper drainage the skull was cut through at the level of the orbital plate of the frontal bone just above the eyebrow, the dura thoroughly opened, and a soft-rubber drainage-tube passed through this opening to the deepest portion of the abscess. The original wound of entrance also gave exit to a drainage-tube. With the exception of a rise of temperature the day following the operation (104° F.) no unfavorable symptoms developed, and the patient steadily improved in every respect. The delirium disappeared after 3 weeks, he became rational, had full control of all his functions, and by October 10 journeyed unaccompanied to his home in West Virginia, where he arrived safely. At the time of his departure there was only a slight superficial granulation tissue about the wound, requiring a change of dressing every 2 or 3 days. This was looked after by his local physician until it entirely healed and the patient was discharged as cured. The wounds were entirely healed, all pain had disappeared, he talked and behaved rationally, and was able to resume his avocation.

While a brain, the right anterior lobe of which had suffered a very considerable loss of substance by traumatism and the destructive process of suppuration with

improper drainage, could not be expected fully to resume its normal function even after removal of the foreign body and with the establishment of thorough drainage and repair of the deep and superficial wound, yet this operation had resulted in the relief of all symptoms of brain disturbance with the exception of a slightly diminished intelligence.

The profession has been made acquainted with the remarkable case reported in the *American Journal of Medical Sciences* for July, 1850, by Professor H. J. Bigelow of Boston, in which there was recovery and resumption of function in a brain in which a large part of one anterior lobe was entirely destroyed. An iron rod 1½ inches in diameter, and 3½ feet in length, had, by the premature explosion of a blast, been driven through the patient's head, entering in front of the angle of

the jaw, passing obliquely upward through the anterior part of the cranial cavity, destroying the left optic nerve and emerging from the top of the frontal bone at the median line just in front of the point of union of the interparietal and frontoparietal sutures. The patient survived this injury for over 12 years, and notwithstanding the loss of so much brain substance from the anterior lobe, was able for a great part of the time to do the ordinary work of watchman and farm laborer. He finally died after a short illness accompanied by convulsions.

The treatment of gunshot wounds of the brain which are not immediately fatal may be considered under two different classes. 1. Those in which the missile passes entirely through the skull. 2. Those in which it lodges within the cranial cavity.

¹ Read at the ninety-eighth annual meeting of the Medical Society of the State of New York.

When a bullet has passed through the skull, the indications are to clear up the wounds of entrance and exit, enlarge these sufficiently to permit the removal of loose fragments of bone which may be driven into the dura or the brain substance near the wound of entrance, to remove any loose particles from the wound of exit, and to arrest by ligature all hemorrhage which may occur in the scalp wounds and in the wounds of the dura. When hemorrhage is occurring from the brain substance no effort should be made to arrest this by plugging either or both wounds for fear of compression upon the brain substance by retained clot. In order, however, to diminish pressure in the injured region and in this way to encourage intravascular coagulation, ligation of the extremities may be practised, in this way holding in the veins a certain proportion of the volume of blood which when the hemorrhage shall have ceased, may be gradually and carefully returned to the general circulation.

The question of drainage is important and the indications are in general met when a few strands of small catgut are placed along the track of the missile in the brain for a short distance and are brought out through the openings in the scalp. Should symptoms of intracranial abscess occur in these cases, the surgical indications are clear that an effort should be made to determine the location of the abscess and institute drainage.

In the second group, those in which the foreign body has lodged within the cranial cavity, any operative procedure must be determined upon by careful study of the conditions which are present. When the missile is of small caliber, and when no hemorrhage has occurred and there is no disturbance of function, I should advise careful antiseptic treatment of the wound of entrance, enlarging it for the purpose of removing any loose pieces of bone which may impinge upon the dura or brain, and of being assured that the foreign body had penetrated beyond the dura into the substance of the cerebrum.

About 1883 a case of this character came under my personal observation. A 26-caliber conical bullet entered the skull of a lad, 9 years of age, just over the middle line of the right eye, passing as well as I could determine from the history of the case and the appearance of the wound, directly backward through the brain. The hemorrhage had been insignificant. There was no paralysis, pain, or loss of function from this injury. Under an anesthetic, 24 hours after the accident, I made an incision, which exposed the wound of entrance through the skull, enlarged the opening with a rongeur, and removed several pieces of bone that had been driven into the dura. As the bullet had passed through this membrane and deeper in the substance of the brain, I deemed it unwise to attempt an exploration. The patient recovered without any unfavorable symptoms, and when I last saw him, 5 years after the accident, he was in perfect health, and had at no time suffered any suggestion of inconvenience from the presence of this piece of lead within the cranial cavity.

When the missile is of larger caliber, or when serious symptoms of injury to the brain are present, the indications are entirely different. The wound of entrance should be thoroughly exposed and cleansed, broken pieces of bone removed, and an effort made to locate the foreign body with a view to its removal.

By means of the radiograph the location of the bullet can be demonstrated, and when this apparatus is at hand no exploration along the track of the missile should be undertaken. When, however, circumstances do not permit the use of the röntgen ray, no better illustration of the method of procedure can be given than by the following instructive case, which was in Bellevue Hospital in 1884, in the service of my former colleague, Professor W. F. Fluhrer. The patient, 19 years of age, received a pistol shot wound, entering through the frontal bone and penetrating the brain. The wound of entrance was enlarged, and a very severe hemorrhage

from a vessel of the pia mater was controlled by a small clamp. A good-sized porcelain-tipped probe was carefully introduced and allowed to find its own way in the track left by the bullet. This instrument passed to a depth of 6 inches, where a slight resistance being met, it was allowed to remain. The direction of the probe indicated the point on the opposite side of the skull at which the missile had most probably struck. Slightly below this level a trephine was applied, and upon removing the disk of the bone the dura appeared dark, from blood effused beneath it. This was incised and the track of the bullet discovered, it having been deflected somewhat lower after impinging upon the concave surface of the skull. This route was followed by the trephine, the bullet found and removed. The probe was now carried entirely along the track of the missile in the brain, and through-and-through catgut drainage established. The patient recovered and returned to his occupation, suffering only with slight impairment of memory and occasional muscular spasms.

In the case which forms the subject of this paper it would have been better to have instituted immediate search for the bullet and to have removed it, for the amount of brain tissue injured in this effort would have been many times less than that which ultimately was sacrificed by the process of suppuration, which continued for several months before proper drainage was instituted; and even had no immediate operation been undertaken, upon the first appearance of the suppurative process, operation should have been no longer postponed.

THE PREVENTION AND TREATMENT OF PUERPERAL INFECTION.¹

BY

RICHARD C. NORRIS, M.D.,

of Philadelphia.

Assistant Professor of Obstetrics, University of Pennsylvania; Surgeon-in-charge, Preston Retreat, etc.

The application of the principles of asepsis to obstetrics has reduced the mortality from infection, in hospital practice, to a fraction of 1%, and our efforts now are to reduce to a minimum the morbidity. The same cannot be said of the results in private practice. A study of the statistics of large cities shows very plainly that almost as many women die from puerperal infection as in former years. This fact is doubtless due to several causes. The careless midwife attends a very large proportion of the foreign elements of population in our large cities; the rank and file of the profession have not learned sufficiently well or disregard the details of strict surgical cleanliness; and the earliest symptoms and signs of infection are disregarded and not promptly treated in time to avert serious and fatal results. These 3 causes are sufficient to explain the mortality which in large communities is not less than 5% of all women dying during the child-bearing age. Before discussing the methods of prevention and the treatment of puerperal infection, it will be necessary to review briefly the latest studies in the bacteriology of the genital canal. The conflicting results obtained by equally competent observers have been disheartening to the practical doctor, anxious to be correctly guided. But it must be borne in mind that the science of bacteriology is relatively young and beset with intrinsic difficulties not appreciated by the uninitiated. Recently, however, there have appeared results that are more in harmony. Errors of technic have been eliminated, and it now appears that the secretions of the vagina, cervix and uterus under normal conditions of health are sterile. The careful work of Krönig, of Menge, and of Williams is the most convincing at the present time. Furthermore,

¹Read by invitation before the southern Branch of the Philadelphia County Medical Society, October, 1903.

Doederlein's investigations have practically established the fact that the normal vaginal secretions, acid, sticky, and gelatinous in character, possess an inhibitory action upon pathogenic microorganisms through the formation of lactic acid by Doederlein's bacillus. The gonococcus is now believed to be the only microorganism that can retain its pathogenic potentialities in the normal vaginal secretions. Similar trustworthy investigations, both bacteriologic and clinical, have demonstrated, on the contrary, that the secretions about the vulva, the vaginal and anal orifices very frequently do contain pathogenic microorganisms, and herein lies the danger, which has direct relation to puerperal infection and the importance of which will appear when we discuss the technic of an aseptic delivery.

The bacteriologic investigations of the infected uterus after delivery are not characterized by conflicting results. Here the findings are rather constant. In 179 cases of puerperal endometritis, Krönig's investigations led him to describe 3 classes of cases—the pyogenic, the gonorrheal, the sapremic. In 79 of the pyogenic cases he found the streptococcus in 75, the staphylococcus in 4. He attributed 50 cases to the gonococcus. In 50 cases, the microorganisms in 43 would not grow in the culture media usually employed, and 32 were pure anaerobes.

Williams studied 150 cases. Streptococcus infection alone was found in 31 cases, associated with other microorganisms in 13. The colon bacillus was present alone in 11 cases; associated with others in 8. In 45 cases the microorganisms failed to grow on the usual media, and 25 cases were sterile. When the streptococcus and colon bacillus were associated, the resulting infection was more dangerous than with either alone. He refers to the dangers of the colon bacillus, and emphasizes the importance of this agent of infection by quoting Gilbert's and Dominici's estimate that an individual excretes from 12 to 15 billion colon bacilli daily, and that the perineum and anus therefore are fruitful sources of infection.

With these facts in mind the discussion of obstetric technic assumes a new importance. Autoinfection becomes a term rarely to be employed, and usually should be reserved for him who wishes a salve for his conscience or a cloak for his ignorance.

The *prevention* of puerperal infection guided by the most recent and reliable results of bacteriology, and of clinical experience requires a study of 3 important details of technic: (1) The antepartum toilet of the patient; (2) hand sterilization and the dangers of vaginal examination; (3) the immediate repair of injuries to the birth canal.

The antepartum toilet formerly required the routine douching of the vagina with antiseptic solutions. Both laboratory and clinical observations have demonstrated that antiseptic vaginal douches are unnecessary, and may be detrimental in normal cases.

The power to destroy pathogenic microorganisms possessed by the normal vagina is lessened by washing away the natural secretion; the corrosive action of the antiseptic upon the vaginal cells lessens the latter's power of resistance to infection; the danger of infection from unclean appliances is especially liable to be found in private practice; and finally the futility of a douche to reach and destroy the microorganisms when they are present is well known. All these facts have banished from the most enlightened technic the routine douche in normal cases. When the vaginal secretions are faintly acid or alkaline and are abnormal in color and consistency—that is, when they are dark-green or brown and of the consistence of cream, or when there is a suspicion of gonorrheal infection—more than a douche is required. Thorough scrubbing under ether with soap and water, alcohol, and mercuric chlorid solution will achieve all that can be accomplished. Even this rigid cleanliness will not always sterilize an infected vagina.

We have learned that the perineum, the vulva and labial folds, in the majority of healthy normal cases, contain pathogenic microorganisms and it is this area and this area only that we should attempt to sterilize routinely. Skin disinfection by any known method is not infallible and herein lies the practical difficulty, and the explanation of the fact that the modern surgeon has been driven to use the sterilized rubber glove. This admission means that were it practicable to apply our best methods of hand sterilization to the vulva and vagina, which for obvious reasons cannot be done without an anesthetic, even then we could not rely upon such methods in all cases. These facts simply fortify the position of those obstetricians—and I am of the number—who believe that vaginal examinations during labor, even with the rubber glove, should be reduced to the least number possible. Were they not necessary at times, for knowledge of mechanism, of progress of labor, and to detect and correct complications, the ideal delivery would be conducted without a single vaginal examination.

And here let me say that I know of no recent detail in obstetric technic more valuable, especially to general practitioners, than the use of sterilized rubber gloves. They should be boiled for each case before they are used and kept immersed in mercuric chlorid solution in the intervals between the examinations that after all are necessary in practical obstetrics outside of hospitals. The danger of carrying infection from the vulvar orifice even on the rubber-gloved finger and of the tendency to careless hand cleaning and handling the glove must not be forgotten.

The third important factor in prophylaxis is the attention required by injuries of the parturient canal. Linear tears of the vagina and perineum should always be united. Contused and ragged lacerations should be neatly trimmed of disorganized tissues before they are sutured. The question of immediate repair of cervical lacerations not producing serious hemorrhage, and of other injuries requiring a formal operation, at this time is debatable. Time does not afford thorough discussion now of that subject. My own conviction is that the dangers of infection, the contused condition of the tissues, the time required and the inopportune occasion in private practice all are in favor of delay until involution of the tissues has occurred.

There are other details of prophylaxis that require close attention. The antiseptic solutions used in the lying-in room for cleaning the hands or genitals should always be made with boiled water. The occlusion vulvar dressings must be changed frequently, and must be made of material known to be surgically clean, otherwise occlusion dressings are best discarded.

All implements, such as forceps, sutures, needles, needle-holder, syringe nozzle and catheter should invariably be boiled before they are used. An occlusion dressing wet with an antiseptic solution should be worn over the vulva throughout labor to prevent the patient from handling the genitals and to disinfect further the commonly infected area—the vaginal introitus.

The questions involved in the foregoing discussion of the technic of the prevention of puerperal infection have induced me to study my own experience at the Preston Retreat, where the responsibility for carrying out the details of the technic employed rests absolutely and only upon myself and my chief nurse. I have, therefore, studied the records in 1,900 consecutive deliveries under my own care with the following results:

In 742 consecutive cases a vaginal douche of mercuric chlorid solution 1 to 2,000 was routinely given to each patient immediately before and after delivery. There was no mortality from infection, and the puerperal morbidity from puerperal infection was 3.7%. That is to say, 28 patients required disinfection during the puerperal period; in 10 cases uterine curetage and an intra-uterine douche of 2% creolin solution were employed;

in 18 cases the vagina alone was disinfected by one or more vaginal douches of creolin, and in some of these cases vaginal ulcerations required applications of zinc chlorid, silver nitrate, or iodoform.

The next 392 consecutive patients received the antepartum mercuric chlorid douche, but the douche immediately after labor was omitted. The morbidity from infection for this group of cases was 3.3%. Of the 13 patients requiring disinfection, 6 received vaginal disinfection alone, and in 7 the uterus was cureted and douched with creolin. The temperature rise in two of the latter cases was subsequently demonstrated, by blood-examination, to be malarial in origin. There was no maternal mortality from infection.

All douches were discontinued in the next 766 consecutive cases, which, of course, included all operative cases, such as forceps, version or manual extraction of breech labors. The antepartum toilet comprised, as heretofore, the thorough cleansing of the vulva, perineum, anus, and vaginal entrance, but the vaginal douche before and after labor was omitted. The puerperal morbidity from infection for this group of cases was 1%. There was no maternal mortality from infection.

Eight cases of infection were noted. Of these three were cases of phlegmasia, one very severe, following a pressure slough of the posterior uterine wall at the site of a prominent promontory, which resulted in a fecal fistula through the uterus. In 4 cases the uterus was cureted and douched, the infection being due in 2 cases to a putrid fetus at delivery, in 1 case to retained membranes, and in 1 case to putrid endometritis. In 2 cases the vagina alone was disinfected. The results are shown in the following table for ready comparison:

1,900 CONSECUTIVE DELIVERIES WITHOUT MORTALITY FROM PUERPERAL INFECTION.

Cases.	Morbidity from infection.	Disinfection of vagina during puerperium.	Curetage and intrauterine disinfection.
Antepartum and postpartum mercuric chlorid douche (1-2,000).....	742	3.7%	2.4%
Antepartum mercuric chlorid douche... Toilet of external genitals douches not given	392	3.3%	1.5%
	766	1 %	.25%
			.5%

It is my purpose to discuss the treatment of puerperal infection in a distinctly clinical and practical manner. Any abnormal puerperal condition must be considered as due to infection until proved otherwise by prompt and systematic examination. Careful inspection of the vaginal mucous membrane from cervix to vulva should always be made with a speculum to detect and disinfect areas of ulceration, from which I have known virulent infection to spread through the lymphatics of the uterine appendages, sometimes permanently injuring the pelvic viscera, and in a few instances destroying the patient. While urging the importance of early inspection of the vagina, it must be remembered that the upper portion of the parturient canal is more susceptible to infection, and on account of its anatomic structure affords easy access to widespread systemic infection. Thus is explained the clinical fact that in the largest number of grave cases, the infection is located primarily in the uterus. Bimanual examination next searches for pain and tenderness in the abdomen and uterus, delayed involution, fixation of the womb or its appendages by inflammatory exudate, and the uterine cavity is explored with the finger to note the character of its contents and lining membrane. The character of the lochia is noted. Whether offensive in odor, frothy, and rather profuse, as obtains when the chill, rapid pulse, and temperature rise, are due to putrefaction of the uterine debris found by the examining finger (sapremic). An empty, relatively

smooth uterus, discharging little and not offensive lochia, accompanied by severe constitutional symptoms, indicates a graver form of puerperal endometritis (septic). For clinical purposes Krönig's three classes of cases of puerperal endometritis are of great practical value—the pyogenic, the gonorrheal, and the sapremic. Gonorrheal endometritis, in the absence of a clear history, cannot be determined without bacteriologic study. Septic endometritis due to streptococcus or colon bacillus infection, when not associated with putrid absorption, usually will be recognized by digital examination. The putrid variety will be recognized by the character of the discharge and the debris, but when associated with the septic variety the latter can only be determined either by the results of treatment or by bacteriologic examination of the uterine cavity. This brings us to an estimation of the practical value of the bacteriologic examination of the uterus, or vagina, or blood-current as an aid to the diagnosis, prognosis, and treatment of puerperal infection. Theoretically it does have a scientific value, but I am convinced that it will only be utilized for research work. Not being available to the mass of practitioners, it is fortunate that practical obstetrics can disregard it. A diagnosis that determines for us the course of treatment can almost always be made without it, and so far as prognosis is concerned, it is well known that patients recover even when streptococci are found in the blood, as well as in the uterus.

After all, a morphologic diagnosis of streptococci, for example, can never be so valuable as a differentiation of their virulence or pathogenic potentialities. Even when the latter is learned from animal inoculation, the outcome of an individual case of infection cannot always be predicted, for it will often depend upon the individual's unknown power of resistance. A clinical diagnosis of the channels through which the infection is traveling is of far greater value for both prognosis and treatment. Determine, if possible, whether the infection is spreading through the lymphatic or venous systems, whether thrombosis and pyemia are present, whether we have to deal with localized or general peritonitis. These problems are of far greater value than a knowledge of the anatomic variety of the microorganism that may be present.

Having made an early diagnosis of infection, the infected area, which is usually within the uterus, should be explored by the finger to determine further, if possible, whether we have to deal with putrid absorption from decomposing debris or the smooth endometrium of septic infection. If our cases always presented the striking contrast and the entire uterine cavity could be easily palpated, as described by some authors, it would at once settle the question of cureting the uterus. While it is true that the endometrium is often smooth and the uterus empty in septic endometritis, and the microorganisms have penetrated the tissues beyond the reach of douche or curet, in very many cases—indeed, in the majority in my experience, such can only be determined by examination under ether (even then with great difficulty), for in most cases there will be found at the placental site and elsewhere, roughened areas which will often leave one in doubt. The reaction that has appeared against the curet is certainly beneficial since we have learned that every patient with child-bed sepsis cannot thus be cured, and that many are really made worse. The dangers of perforating the womb, of carrying infection into the uterus through ignorant and faulty technic, of opening new avenues for absorption of toxic agents already present in the uterine or vaginal canal, of destroying the lymph barriers erected by nature to cut off lymphatic or circulatory absorption—all these real dangers should not deter us from utilizing a valuable means of treatment at the right time and in the right manner in the right cases.

The appropriate cases are those in which the uterus contains debris, often so closely adherent to the uterine

wall, that I am at a loss to understand how such removal can be efficient with the finger as is insisted upon by some able writers. The finger should try to locate the areas to be cureted, and in my experience the best results have followed the use of a sharp curet. Where the endometrium is smooth, of course there is no need for scraping. I have yet to see the case of puerperal endometritis after labor at term that shows the continuously smooth uterine cavity sometimes described by those who have no use whatever for the curet in puerperal sepsis. The danger of destroying nature's lymph barriers has been overestimated. This protecting zone is present especially in sapremia, the very class of cases to which the curet is applicable and in which it can do the least harm. The curet should be used by the skilled and experienced hand. In these cases curetage is not a minor operation and demands far greater surgical skill than the formal plastic operations of the gynecologist. The third condition for its successful use is that it should be used at the earliest possible moment after the diagnosis of infection has been made and after exploring the uterine cavity with the finger as thoroughly as possible. Following curetage, the question of the douche is also under discussion at the present time. For putrid endometritis a disinfecting douche is, in my experience, indicated. The patient must not be poisoned, and strong antiseptics that aim to destroy virulent microorganisms, which, as a matter of fact, in the septic variety, have passed into the tissues beyond the reach of the douche, are not only useless, but dangerous. Weak solutions of lysol (1%) or creolin (2%) are sufficient to combat putrefaction and can be used with safety. A gauze drain is then inserted to the fundus and removed in 24 hours. When, as rarely happens, we find the uterus empty neither curet nor douche are indicated. When indicated, the operation to achieve the best results must be done early and thoroughly, and should almost never be repeated. Repeated douching will be required very rarely, and only when an offensive discharge persists.

Turning now to the surgical treatment of puerperal infection we have problems, some of which have been definitely settled, and others which offer wide differences of opinion and practice.

Salpingitis that progresses to abscess formation requires evacuation and drainage, in some favorable cases, by the vagina, but more often an abdominal operation is preferred because of the uncertainty of exact diagnosis. General peritonitis rapidly developing from extension through the tubes or uterine wall will usually be fatal unless the surgeon is most aggressive and operates within the first or second day of the appearance of the grave symptoms. Rapid respirations (50-60); a weak, rapid and compressible pulse (150-160); a leaking skin and the characteristic facies of overwhelming sepsis are enough to predict a surgical failure and a fatal termination.

No one doubts the necessity for removal of ovarian or uterine tumors, injured or infected after labor. Extraperitoneal collections of pus are best removed by an extraperitoneal operation, an abdominal section being necessary sometimes to make an exact diagnosis. The foregoing surgical problems are fairly well determined and require no further discussion.

Hysterectomy for puerperal infection is by no means a settled question. All surgeons, I believe, agree that it is indicated when tubal or ovarian abscesses have been removed and there will be left behind in the pelvis, infected and infiltrated broad ligaments or a uterus containing areas of infection or suppuration which will finally spread to the peritoneum or permit septic absorption to continue until the patient succumbs. There is a difference of opinion as to its usefulness in the early cases of grave infection going from bad to worse under the usual treatment by curetage, irrigation and stimulants, in which cases there are no physical signs indi-

cating that the local septic process has spread beyond the womb, and for which immediate hysterectomy is performed (usually within the first week after delivery) in order to terminate abruptly septic absorption in time to save the patient's life. Such cases include especially the grave forms of septic endometritis in which the infection is yet limited to the uterus; cases in which the sloughing placental area is not removable by intra-uterine operation; cases of single or multiple abscesses in the uterine wall; and cases of uterine phlebitis before dangerous pyemic symptoms appear.

A few such patients have been successfully operated upon, but the practical difficulty is their diagnosis. Even when the diagnosis can be made, the necessity for hysterectomy to save life is not always plain.

Bacteriologic examinations of the blood and uterine contents, as made by Roux, Widal, Marmorek, and others, have utterly failed to settle this question. Pathologic anatomy has also failed to point to any definite indications. Clinical symptoms and signs, which thus far are the most reliable, seldom make the operation unmistakably necessary. Once in a great many cases a skilled surgeon who also has a wide experience in obstetrics, will by exclusion select hysterectomy and find he has not made a mistake. Usually the operation is determined upon too late or is unnecessary. Statistics of the relatively few operations performed up to the present time, show that abdominal hysterectomy for these cases has a lower mortality than vaginal hysterectomy. Fehling¹ collected 61 cases by 53 operators. In 19 abdominal total hysterectomies the mortality was 31.5%; in 33 vaginal hysterectomies, 69.6%. Jewett² collected 62 abdominal hysterectomies with 38.7% mortality; 25 vaginal with 52% mortality.

Ligation or excision of the uterine or spermatic veins when they are the seat of thrombosis with pyemic symptoms is the latest attempt to reach by surgery a very dangerous type of puerperal infection. The results of ligation of the internal jugular vein for pyemic thrombosis of the transverse sinus following purulent otitis, induced Trendelenburg³ to ligate the uterine and spermatic veins with success, having observed thrombosis of the uterine and spermatic veins in 21 of 43 fatal cases of puerperal sepsis, with only 4 of the cases combined with lymphatic infection. At the Rome congress this subject was discussed with favor and offers another important problem in the surgery of puerperal infection. That its usefulness will be limited, would appear from the facts that the thrombus may be beyond reach by the time there is evidence of pyemia, and that at present we cannot always make the diagnosis or predict a necessarily fatal termination since many patients with puerperal pyemia recover with the usual treatment by stimulants. Here again, diagnosis is the stumbling block. Wide fluctuations in temperature, repeated severe chills, a slower pulse than one would expect, an empty, freely movable normally involuting uterus, a pelvis and abdomen free from localized infection, all point to a pyemic process, and excision of a thrombosed vein should be borne in mind. The great number and inaccessibility of the veins involved (in 21 autopsies the thrombosis was bilateral in 14) renders the operation very difficult and although the thrombus tends to remain localized for a relatively long time, extension was found in 4 patients operated on by Trendelenburg with a fatal result. He had one brilliant recovery. The future must decide this question. At present it will require a bold surgeon to save these patients.

The constitutional or general treatment of puerperal infection requires little discussion. Easily digested or predigested food to the tolerance of the stomach, and free stimulation are, after all, our sheet anchors in these grave cases. Alcohol in large doses, but not enough to

¹ Monats. für Geb. u. Gyn., October, 1902.

² Am. Gyn., February, 1903.

³ Münch. med. Woch. April 12, 1902.

produce its untoward physiologic effect, digitalis, quinin, strychnin, nitroglycerin, ammonium carbonate by the bowel, and inhalations of oxygen will be useful. An ice coil to the abdomen, and the free use of subcutaneous or rectal injections of normal salt solutions, are of distinct value. High enemas of salt solution not only are absorbed to dilute and help the elimination of toxins, but serve the additional purpose of lavage of the intestines, which is very valuable for patients who are ill for a long period. Serum therapy has been wholly disappointing, and practically has been discarded. I have employed intravenous injections of formalin in salt solution, but with no results that I have not observed after salt solution alone. The intravenous injection of any antiseptic in sufficient strength to destroy virulent microorganisms or their products would in all probability destroy also the blood, and I have thought such treatment productive of more harm than good. Inunction with silver preparations has but few advocates, and the production of leukocytosis by nuclein has not been demonstrated to be of real value.

In conclusion, let me say, that while the problems referred to are being determined by the pathologist, the surgeon, and the obstetric clinician, it is our duty not to forsake old methods for any new method of treatment and not to lose sight of the fact that many lives have been saved by local antisepsis, intrauterine treatment, the curet, or other surgical means in proper cases, early and skilfully applied. The gravest forms of puerperal infection can very often be prevented by the early recognition of beginning infection and the prompt resort to our well-tried methods of treatment.

MYXONEUROSIS INTESTINALIS MEMBRANACEA.*

BY

PROFESSOR DR. C. A. EWALD,
of Berlin, Germany.

A catarrh of the intestine, especially of the lower portion, is very often combined with secretion of mucus or accompanied by glairy, unformed or string-like masses, sometimes ragged particles. Microscopically, small portions of mucus contained in or surrounding the fecal masses, are also seen. They are easily distinguished from similarly appearing food particles through their opacity upon the addition of acetic acid.

When the mucus is mixed thoroughly with feces, then one may conclude that the lower portion of the small and the upper portion of the large intestine are affected. The passage of pure mucus without feces, or small hard balls of feces which are enveloped in mucus, indicates catarrh of the lower portion of the colon. The more muscle fibers and starch granules found, the more is an affection of the small intestine to be considered. Soft masses of mucus and small pieces of tissue are characteristic of catarrh of the small intestine. Larger and more solid dejections, which are formed in the pouch-like portion of the colon, indicate a catarrh of the sigmoid and rectum.

There are two entirely different types of disease which are combined with discharges of mucus and accompanied by colicky pains:

1. During the course of a simple catarrh we find sometimes acute boring or griping pains in the left side or in the left epigastric region, which may last for days. We call these *Colica intestinorum*, and when accompanied, as ordinarily, by an increased amount of mucus, *Colica mucosa*. The cause is always a catarrh or inflammatory process, which affects the mucous membrane of the intestine—an enteritis.

2. In counterdistinction to this group is another characterized by the appearance at first of a mucous discharge, which may be sometimes, but not always, followed by

an enteritis. That is to say, a secretion neurosis which, as a functional disturbance, produces an abnormal amount of mucus. It may happen, as in other functional disturbances, that an intercurrent and anatomic condition may appear during the course of the disease. There is no difference between the findings of this disease and those of enteritis or *Colica mucosa*. This group of symptoms I have called "*Myxoneurosis intestinalis membranacea*," a name which clearly points out the character of the disease.

These 2 unique pathologic anatomic conditions were described, one by O. Rothman and the other by M. Rothman. Membranous enteritis depends upon a pathologic change in the intestinal mucosa, while in the condition described as myxoneurosis intestinalis the mucous membrane is normal. In both cases the stools are, aside from a small amount of fecal matter, composed almost entirely of mucous masses.

They are composed of tenacious mucinous bodies plus fibrin in small amount, nuclealbumin and globulin. The mucin can be differentiated from the fibrin by using triacid stain. The histologic peculiarities of these slimy masses have been studied by Wolf, Ewald, Nothnagel, A. Schmidt, Westphalen, and others. They consist of a homogeneous, somewhat opaque ground substance which is interspersed with cell detritus. This detritus is composed of nuclei which are recognized because of their strong refractile properties, cell elements, epithelial and round cells, as well as peculiar shining flakes which are thought to be due to hyaline degeneration or an imbibition of soap. The epithelial cells usually show granular degeneration, are without demonstrable nucleus, vacuolated, and frequently broken up. Beside these, there are cholesterin crystals, needles of the fatty acids, triple phosphate crystals, particles of undigested food, bacteria, and occasional red and white blood cells. It sometimes happens that there are sand-like concretions which resemble ground white pepper, and are easily mistaken for the seeds of strawberries or currants, but their character can be proved by the addition of acetic acid, in which they are soluble.

There are a great many reasons why this myxoneurosis is of a nervous nature. The cases are most frequent in women, and are frequently accompanied by some genital disturbance; coming especially during the climacteric and disappearing when this period has passed. A pronounced constipation of nervous origin, paralysis or spasm is a frequent cause. However, there are isolated cases in which there is an intercurrent nervous diarrhea present, or sometimes in the same patient there may appear a membranous enteritis, which disappears in a short time, and pure myxoneurosis remaining for some years.

Einhorn and myself had under observation patients in whom were combined an achylia gastrica and a nervous diarrhea. Cases combining the so-called nervous dyspepsia and enteroptosis also point to the nervous nature of the affection. The colic accompanying these cases is only one manifestation of the general nervous condition. Other symptoms of a nervous nature usually predominate, and the slimy stools may not be noticed, or, if so, only accidentally. In other cases there occur, in a rather regular manner, intermittent pains which are of a colicky nature. They come on sometimes suddenly and sometimes gradually, and are situated in the left side of the abdomen, may be diffused, or be radiated down the thigh. They may sometimes occasion bladder symptoms.

Most frequent, however, is the stubborn constipation. The mucous masses are discharged either with the stool or directly following. Sometimes, however, the call to stool may be rewarded only by the passage of the mucous masses. The colicky attacks may simulate an enteritis accompanied by slight fever, dysentery, or even typhoid fever. Also perityphlitis (Solis Cohen) or the so-called pseudo form of gallstone colic, especially when the pain

* Translated by C. O. Bechtol, of Chicago.

is located in the upper right quadrant of the abdomen. It is scarcely conceivable that these relatively small secretion anomalies could produce lasting injury, but it frequently so happens. Moreover, it happens that this disease is especially stubborn and extremely capricious in its coming and going; however, it does not threaten the life of the patient or weaken the strength of the organism. In case the latter should happen, it is due to primary nervous affection, and the patient may suffer severely, and the affection be a source of continuous annoyance and depression.

The therapy has the following problems to solve:

1. The intestines must be emptied without the use of strong, and especially, without saline agents.
2. The pain should be overcome without the use of narcotics.
3. The sequels of the obstipation, *i. e.*, gas formation, dyspeptic symptoms and autointoxication must be obviated.

To accomplish these things a great many methods may be employed, but especially recommended are vegetable laxatives, such as senna, castor-oil, flaxseed, etc., and proper regulation of the diet. Laxatives are objectionable because they must be given in increasing doses, and are not then followed by a cure. Injections of oil, as recommended by Kussmaul, are especially valuable and are given as follows: 300 cc. to 500 cc. of slightly warmed linseed, olive or sesame oil is injected high into the rectum by means of a soft rubber tube (not a hard rubber canula) while the patient lies on the left side. The injection should be made slowly, the patient remaining on the left side for about 10 minutes, and the enema should be retained as long as possible. It is only after this means has failed to produce a good movement that catharsis should be resorted to and some aperient mineral water be given.

Diet in all these cases plays a very important part in the treatment. When we remember that myxoneurosis is most frequently associated with obstipation, it is evident that food having some cathartic action is desirable. Remembering also that some patients are not constipated, it is easy to see that a fixed diet will not suit all instances. If the trouble is characterized by obstipation which is due to a simple intestinal inactivity or primary weakness of the intestinal muscles or secondary hysteric or neurasthenic disturbances of innervation, the diet would naturally be different from that in a case in which the disturbance was due to some mechanical hindrance as from the uterus or adnexa.

Recommended as specially efficacious when simple constipation accompanies the myxoneurosis, are the coarse breads, as black bread, graham bread and rye bread; fats, as butter, cream, or lard, salads with oil, fatty sauces, gravies; coarse vegetables of the cabbage family; curded milk with plenty of sugar; fruit juices, figs, syrup, jams, prunes, stewed fruits, and fresh vegetables of all kinds. If taken in the morning on an empty stomach, the following are frequently of value: Strawberries, raspberries, currants with milk or cream, or gooseberries, oranges, melons, grape fruit and apples. This diet acts not so much through the mechanical irritation of the coarse flour and seeds contained in it, as through the formation of gases and acids which stimulate peristalsis.

Most of these dietetic measures are known to the laity and especially to the patients themselves who have for a long time tried various foods and remedies for their trouble. The success of such a diet depends upon the exactness with which it is followed, for it can be hindered by the eating of various constipating foods, and such things should be naturally prohibited.

Such a regimen may be either gradually or immediately instituted. It happens unfortunately, according to my experience, that with such dietetic measures alone the results are not satisfactory, and that other means must be used in order to bring about the desired cure.

For this purpose, beside the diet recommended, it is well to employ some of the following measures: Mineral waters, massage, electricity, room gymnastics, or some of the various cold water treatments, especially the Scotch or alternating hot and cold douches. It is self-evident that such a diet is not practical in all cases, particularly those in which the action of the stomach is disturbed through food digested with difficulty. The patients with spastic constipation are also made worse by such coarse diet. When a spastic constipation exists and its nature is understood, opium and belladonna internally, or in combination as suppositories, employed along with injections of oil, work very well. When these measures, plus a coarse diet, produce a cure in a case with spastic constipation, it is in spite of the diet and not because of it.

It is only rational that in these last-named cases a mild, nonirritating diet should be instituted, which through its nonirritating qualities produces a laxative effect. This diet may be followed whenever constipation does not exist—a so-called lactovegetable or even constipating diet. The following diet scheme recommends itself for this purpose: Breakfast: Sweet milk, cocoa, oatmeal with cocoa, white or dark bread, with honey, jam, or fresh fruit. Dinner: (preferably at midday) Vegetables or fruit, as apples, plums, blueberries, raspberries, cherries, a broth or vegetable soup, spinach, tomato, or beet soup, a milk soup, or curded milk, butter, and a liberal amount of fresh vegetables are desirable, or pea, rice, or lentil soup, stewed vegetables with dumpling, macaroni, puddings, blanc mange with fruit juices, etc.; salads, and eggs variously prepared, bread with butter, and a light cheese. Supper: A thick soup, made with barley, rice, tapioca, etc., baked potatoes, eggs, bread, butter, cheese, milk, etc.

According to the needs of the patient the foregoing diet will be more or less carefully followed, and on certain days a small amount of meat may be allowed by way of variety.

While this diet is directed especially against the local intestinal condition, still it serves well to support and improve the general nutrition, because of the high percentage of carbohydrates and fats, which is very important. These are of special value in instances in which women have had repeated pregnancies, and as a consequence have pendulous abdomens with low-hanging intestines, in which the feces tend to stagnate. Through improved nutrition it frequently happens that the abdomen takes on fat, making the walls more firm, and consequently raising the intestines somewhat, thus indirectly relieving the constipation. In the cases not complicated by costiveness the results of dietetic treatment are not marked. However, through better nourishment the hysteria and neurasthenia are directly benefited.

SUBURETHRAL ABSCESS.

BY

RICHARD F. WOODS, A.M., M.D.,
of Philadelphia.

Suburethral abscess is an infrequent and very interesting condition. The subject is one that has received little attention, and I find that it is not even mentioned in the majority of textbooks. The following case is therefore of considerable interest:

CASE.—M. T., a white married woman, aged 36, presented herself at the gynecologic clinic of the Pennsylvania Hospital and gave the following history:

She has had 4 children and 1 miscarriage. Six months previous she began to suffer from painful and frequent micturition, the pain occurring during the act, and continuing for some time afterward. After 2 or 3 weeks she noticed a swelling in the vaginal vault, which increased in size until she came to the hospital.

When I first saw her the physical signs were as follow: A rounded egg-shaped mass was seen protruding from the vaginal

vault. It was red, tense, and painful on pressure, and poorly ribbed with the vaginal rugae. It extended back apparently to the cervix, which could not be seen or felt, owing to the intrusion of the mass in the vagina. When catheterized, the urine was found to be clear and healthy. She was advised to remain in the hospital, but refused. She was not seen for 3 weeks, when she again presented herself at the clinic. The mass at this time was found to have decreased in size, but retained most of the characteristics found at the first examination (the appended sketch was made at this time and not at the first examination). However, a positive diagnosis was made by the discovery of a small opening, just within the urethral orifice, which exuded pus when pressure was exerted on the mass in the vaginal vault. A probe was passed through this opening, and entered a large cavity. Firm apposition with the probe against the abscess wall could plainly be seen and felt through the thickened vaginal mucous membrane. A sound passed along the anterior urethral wall directly entered the bladder. The urethra did not seem to be dilated along its course to any extent. The case was, therefore, not one of urethrocele, but a suburethral abscess, occurring in the urethrovaginal septum.

The patient absolutely refused to have any radical means taken for her relief and left the clinic.

The symptoms of suburethral abscess are usually the same in all cases. There is progressive, painful, and frequent urination. The urine may be mixed with pus, or it may come away clear, more frequently the latter is the case, unless pressure is made over the tumor. Generally there are no constitutional symptoms, a febrile condition being rare. (In Cory's case, however, there was fever, loss of appetite, great thirst, and considerable delirium.) After a time a tumor is noticed protruding from the vagina. It varies in size from a hen's egg (Tait and Thomas) to the size of a marble (Routh).

In all advanced cases there is dyspareunia. In the majority of cases pressure on the tumor will cause pus to flow out of the urethra; sometimes a change of position may empty the sac; occasionally the pus may recede into the bladder, causing a cystitis. The smoothness and elastic hardness are rather characteristic of this condition. In examining the urethra, a sound can generally be passed through the opening in the urethra into the abscess cavity, while a sound passed along the anterior wall will travel directly into the bladder. In a great proportion of these cases there is no dilation of the urethra. The sac usually contains decomposed urine and pus; calculi are sometimes present. Priestley found the cyst contained sebaceous material in one of his cases. The walls of the sac are usually smooth and glistening, but they may be rough and granular. They are very thick and tough. There is generally only one opening from the pus cavity into the urethra. (In Routh's second case there were two.)

It is rare for the abscess to rupture into the vagina, although this occurred in one of Tait's cases. On examination he found a hole the size of a shilling in the vaginal wall of the abscess. His finger was admitted into a large pear-shaped cavity, with the apex up toward the urethra.

In the majority of cases the diagnosis of suburethral abscess is comparatively easy. In urethrocele the whole posterior wall of the urethra is stretched and relaxed, while the urethral canal is dilated along its whole course. Abscesses occurring in the lacuna of Morgagni are small and can not be observed from the vagina. A cyst of Gärtner's duct is also small (about the size of a marble) and has no communication with the urethra. (Veit, Boys deLoury, and Kiwisch all report cases of the latter.) A cyst in the vaginal vault could be easily differentiated owing to its thin walls, absence of pain, and, in the majority of cases, the failure to express pus from the urethra on pressure.

In some cases, an abscess in the urethrovaginal septum, has been caused by a stone in the urethra. Chéron reports a case of this kind in which a hard lump in the anterior vaginal wall turned out to be a stone encysted in a sacculation of the urethra. In Gentle's case there was a tumor in the vaginal vault, and symptoms of calculus; a catheter introduced into the urethra discovered the stone. Giraud also reported a case in which a foreign

body was felt in the urethra, the woman had been kicked 4 months before, a calculi was removed through the dilated urethra.

The microscopic appearance of the sac in a case of his is described by Kelly as follows: "On the outer vaginal surface a typical mucous membrane; beneath, the connective tissue rich in oval and spindle cells, with numerous dilated bloodvessels. The inner lining of the sac consists of mucous membrane eroded in places, and beneath this are irregular aggregations of polynuclear leukocytes, and the surface is rough with many elevations and depressions. In some of the depressions irregular oval cells with small oval nuclei are found either in short rows or scattered without order appearing identical with urethral epithelium." The average period in which this condition may occur is from 30 to 50. De Bary reported a case in a child 1 year old. This is probably the youngest patient whose case is recorded; while Chéron reports a case in a woman of 68.

It would be perhaps of interest to review some of the reported cases and recall their important characteristics.

The first case reported was in 1805 and was described by Hey. The woman had been troubled for 15 or 16 years with sudden and irregular discharges of purulent matter from the vagina. He found a roundish tumor at the os externum which when compressed yielded pus from the urethra. The urine when drawn did not contain the least mixture of purulent matter and he could pass a probe easily to the most dependent part of the tumor. He divided the tumor longitudinally and packed it. The woman made a speedy recovery. Since Hey reported his case there have been about 38 cases all told in medical literature. Routh reports 3 cases as follows: In his first case examination revealed granular endocervicitis and a urethral diverticulum the size of a marble. After local treatment for 3 weeks without benefit, the sac was dissected out per vaginam, and one gut suture was used to draw the vaginal wound together. The urine was drawn regularly and the wound healed nicely. Dr. Boulton who examined the specimen thought that it was originally a blood cyst, the result of injury during parturition, and that connection with the urethra was due to suppuration, inflammation being kept up through the access of urine to the sac.

In the second case the symptoms were as usual, the mass being about the size of a walnut. The abscess which was found to communicate with the urethra by 2 openings was dissected out. The third case was identical with the other 2 in regard to symptoms and physical signs; efforts were made in this case however to apply caustic to the cavity by dilating the anterior part of the urethra, this failing Routh operated as before.

Santesson's case dated from a confinement 3 years previous. The physical signs were typical except in the fact that pressure on the swelling caused its contents to flow back into the bladder. After 4 years of palliative treatment an elliptic piece was cut from the vaginal wall, the wound being united by sutures. The patient died 6 years after the operation, of cystitis and nephritis. Santesson, long after this, made the statement that in future cases he would remove the whole diverticulum, suture the margins of the wound, and keep a catheter in the bladder until union was accomplished. Baldy reports a case in a woman who had been operated on some time previous for pelvic inflammatory disease. On examination he found a thickened, indurated, and fluctuating broad ligament, and in addition a bulging tumor extending from urethra to cervix. He opened the abdomen, which was explored and closed. The anterior

lip of the cervix was then amputated; pus was found and continued to flow for a week, when the cavity was finally opened, washed, and drained.

William Priestley described in 1869, 3 cases. The first patient was 8 months pregnant. When labor came on the vaginal swelling ruptured and a quantity of thick pus was discharged from the urethra. In the second case sebaceous matter was found in the material from the cyst. In Hickenbotham's patient cephalotripsy was performed on account of a hard contracted cervix. The tumor ruptured into the vagina on the tenth day. Tait who was called in consultation, found on examination a mass protruding from the vulva with a hole the size of a shilling punched in it. Tait opened up the whole cavity, dissected out the mucous membrane and united the flaps by suture. This case with those reported by Priestley, Foucher, Galabin, and a case of Englisch's all were discovered before rupture had occurred into the urethra. In 1875 Tait published his first case. Ten years after, three others were reported by him. The symptoms of his patients were all alike and typical. The first case was of long duration. He treated all the patients (in the same manner) by cutting out an elliptic piece of the vaginal wall of the abscess and uniting by silver wire. He noted in all these cases the accompaniment of a remarkable amount of bleeding, altogether disproportionate to the operation.

Skene Keith's patient had one symptom, which is rather uncommon, involuntary passage of urine. This case was also complicated by prolapse of the uterus. He cut down in the median line and the mucous membranes of the urethra and vagina were sewed together, to prevent the too rapid closure of the wound.

Thomas attended a negress suffering from painful urination and cystitis. The vaginal canal was occluded by a tumor the size of a hen's egg. He removed the whole portion of the vaginal wall which constituted the tumor, and brought the lips together with sutures.

In Cory's case the constitutional symptoms were more marked than in any of the other cases. There was flushing of the face, delirium, and great thirst. In a violent fit of retching the sufferer felt something burst, which gave her immediate relief. Cory found a small rent within the meatus, $\frac{1}{2}$ inch from the orifice, with pus exuding on the slightest pressure. Cory did not operate on this patient, but the wound healed without trouble. Hermann treated his patient by dilating the urethra, and rubbing the interior with a solid stick of silver nitrate. In Englisch's case there was no communication between the abscess cavity and the urethra. In one of Galabin's cases he found the abscess cavity communicated with a tube, which extended toward the cervix, and contained purulent matter; there was no communication with the urethra. There is a possibility that this case might have been originally a cyst of the duct of Gärtner.

Cullen reports a case of Kelly's in which the patient had the ordinary symptoms. The swelling was 3 cm. by 2.5 cm. in the vagina, was just behind the urethral orifice, and communicated with the floor of the urethra. In Winckel's case the woman cured herself by applying lead-water poultices after repeatedly emptying the sac.

The cause of suburethral abscess is more often attributed to infection of the glands, ducts, and lacunae of the urethra than to any other cause. We find in reviewing the glandular anatomy of the urethra why this should be the case. Skene's glands, which are two in number, running parallel to the anterior third of the urethra, having their openings just within the urinary meatus, are often, from their exposed position during coitus liable to become infected. Littre's glands are also apt to suffer the same consequences. These glands are very numerous, there being 25 of them, but they are merely reduplications of the mucous membrane. Morgagni's glands also are numerous, and open by small ducts in the urethral floor.

Kelly believes the origin of suburethral abscess is in an infection of Skene's glands. I am inclined to think that this occurred in the case I reported. I believe the infection was gonorrheal, infecting the glands and closing their openings, a small abscess resulted in the gland, which ruptured into the surrounding tissue, became larger, and involved the entire septum, and finding the urethra less resisting than the vagina opened in that direction.

Routh thinks the causes are: (1) Closure of the ducts of preexisting urethral glands, retention cysts resulting, with suppuration and ulceration into the urethra; (2) blood cysts which have passed through similar changes; (3) the formation of pseudocysts by injury to the urethral floor during labor or instrumentation.

Parrish, Chéron, and Jenks all agree that the origin is (1) congenital; (2) caused by union between the urethra and a preexisting noncongenital cyst of the vagina; or (3) determined by a limited tear of the urethral floor during labor.

Boulton believes that the abscess which he examined was caused by a blood cyst, while Santesson suggests that it might be caused by an injury to the urethral floor.

Priestley believes his case arose from the follicular structure of the urethra.

Tait views the origin as follows: (1) That there is an error of development by which a small offshoot of the urethra, like a diverticulum of intestines, becomes infected with urine; and (2) that it is caused by the union between the urethra and a cyst of pathologic origin in the roof of the vagina.

Mann believes with regard to the diverticular form that a cyst of the urethra, probably congenital, has subsequently opened into the urethra.

Englich, of Vienna, writes of seeing these cysts with comparative frequency in the newborn; and it is possible, as Mann and English suggest, that they may give rise to this condition.

Of especial interest in this connection is the persistence of the duct of Gärtner and its relation to Skene's glands. According to Dohrn there are only 2 instances recorded of the persistence of this duct in adult women. One case is based on an apparently accurate record of a dissection made in 1559; the second is described by Furst, in a German work published in 1868. Fischel, Beigel, Dohrn, and Reider, all have failed to trace Gärtner's ducts lower than the highest portion of the vaginal walls, near their reflection on the cervix, and have not been able to trace them to the urethra.

There has been some difference of opinion in regard to the termination of Skene's tubules; some believe that they are the termination of Gärtner's ducts; others that the ducts of Gärtner disappear near the cervix, and that Skene's glands are the outlet of a pair of glands lying in the walls of the urethra. Skene himself believed them glands. He says: "I have called them glands because they differ in size and structure from the simple follicles found in abundance in the mucous membrane." Gärtner's ducts are generally thought to be the homolog of the vas deferens in the male.

Bland Sutton found in an examination of 70 cows that Gärtner's ducts became incorporated with the cervix, the lumen of the ducts being obliterated. In a few cases, however, they opened on the mucous surface of the vagina; in older cows he found the duct obliterated and the persistent portion of the duct dilated, especially at the cervix and vagina, forming cysts, which in some cases were as large as oranges, and bulged into the vagina.

Max Schuller has traced Skene's glands upward into a pair of true tubular glands, and he has failed to find any communication between them and the ducts of Gärtner.

The treatment of this condition, which seems in all cases to give the best results, is an elliptic incision which removes the vaginal portion of the sac. The

cavity should then be cleaned thoroughly and the edges drawn together with silk sutures; a small drain may be introduced. The bladder should be emptied by catheter for 6 or 7 days.

THE VALUE OF HISTOLOGIC EXAMINATION IN CARCINOMA OF THE UTERUS.*

BY

BROOKE M. ANSPACH, M.D.,

of Philadelphia.

While röntgen ray therapy seems to have increased the armamentarium of the physician against carcinoma, the chief remedial agent today is found in surgical intervention. Many operations have been devised for the complete extirpation of carcinoma of the uterus. The fact remains, however, that a large proportion of the cases which reach the surgeon are incurable. This statement applies more to carcinoma of the cervix than to carcinoma of the fundus. It need not be proved that the earlier a case of carcinoma of the uterus falls into the surgeon's hands, the more favorable it is for cure. No matter how extensive the radical operation may be, if the carcinoma is of any age, its recurrence is more or less a matter of time. A large number of those who formerly practised the extensive radical operation for carcinoma have finally become convinced that if the disease has once advanced beyond the limits of the cervix, the case, so far as a permanent cure is concerned, is hopeless.

The reason for this is, that in the extension of a carcinoma we are dealing with an extension that involves histologic elements. When once these elements pass the confines of the cervix they invade the pelvic tissues in such a manner that their detection and complete removal is practically impossible. Thus the carcinoma cells may not only be deposited in any of the lymph-glands of the pelvis, but they may indeed grow along the lymph radicles themselves, as described by Mackenrodt, H. W. Freund, and Russel. Ernst has shown that the malignant cells also invade the nerve sheaths.

If, therefore, all the glands of the pelvis could be extirpated in the radical operation for carcinoma of the cervix, there would still remain the lymph radicles. Olshausen, Hofmeier, Van Ott, Richelot, Carstens, and Jordan believe that no operation, for carcinoma that has extended beyond the cervix, can be complete enough. Some operators (Kroenig¹) believe that if the grossly diseased parts (enlarged pelvic glands and parametrium)

are extirpated with the uterus the carcinoma cells remaining behind in the lymph radicles, etc., may be destroyed. If, however, one would confine his attempts to the removal of the enlarged glands alone, he should remember that some of the enlarged glands in uterine carcinoma are not carcinomatous, and, on the other hand, some of the diseased glands are normal in size.

Zweifel² and Schauta³ are inclined to look upon carcinoma of the uterus as analogous to carcinoma of an abdominal viscus, and to regard extirpation of the pelvic glands as offering little hope of cure.

Many times it is impossible to say from clinical means whether there has been any extension of the carcinoma into the parametrium. Kundrat, whose work will be described more fully later, found that even in the absence of induration there might be invasion of carcinoma in the parametrium, and, *vice versa*, that induration itself, if present, might be due to inflammatory reaction of the paracervical tissues.

It is probably the consensus of opinion that unless carcinoma of the cervix is strictly confined to the limits of the cervix, the prospect of cure, even after the most radical procedure, is very small. Although the advanced radical operation for carcinoma is still too young to speak definitely of its success or failure, it is only reasonable to suppose that its application does result in less recurrences than did vaginal hysterectomy; this is true because by a wider resection of the pelvic tissues there is more chance of extirpating all of the carcinoma cells. It is needless to say that if in any given case one could determine absolutely that the disease was confined to the cervix, vaginal hysterectomy or even amputation of the cervix would do quite as well as the most radical operation. The keynote to the possibility of curing carcinoma by surgical means lies in its early recognition. One has only to observe how often the disease comes to the surgeon after it is inoperable. Statistics concerning the percentage of operable cases are misleading because different surgeons recognize different bounds of operability, and this is especially true since the development of the modern operations.

Kundrat,⁴ an assistant of Wertheim, who advocates the advanced radical operation, has examined the parametrium in 80 cases of carcinoma of the cervix in which operation was done at Wertheim's clinic. His results afford a reliable opinion as to the operability of these cases, assuming that they are inoperable when once the growth has extended beyond the cervix. In but 32 of these 80 cases were the parametrial and glandular structures of the pelvis found free from carcinoma.

In reaching this conclusion, Kundrat examined the parametrium and glands of each case in serial sections, examining for this purpose 21,000 preparations.

The percentage of operability, therefore, in Wertheim's cases of carcinoma of the cervix is 40—assuming that after the disease has advanced beyond the cervix the case is hopeless. These figures of Kundrat may be accepted as being nearly correct. He says in his paper that every patient at Wertheim's clinic is operated upon whether the disease is far advanced or not. But there must be some advanced cases in which the radical operation would be unjustifiable, so that we may regard Kundrat's percentage of operability as somewhat high. It would seem true, however, that the actual operability of cases of carcinoma of the cervix does not exceed 40%.

If results in the surgical treatment of carcinoma of the uterus are to be improved, the number of operable cases must be increased, for it is in these alone that there is any reasonable hope of cure. An early recognition of carcinoma is, therefore, of prime importance. There must be an early stage in every case of carcinoma in which it might be recognized by using the means at our command.

Israel,⁵ who recently discussed the etiology of carcinoma, concluded that its origin was directly related to the biologic properties of epithelium. After the embryo-

* Read before the Philadelphia County Medical Society.

logic development of the epithelial or endothelial covering, the cells remain inactive, except when their multiplication is necessary to cover some area that has become bared. More proliferation than is necessary to make up for the defect is common.

So long as the epithelial proliferation and the connective tissue hyperplasia remain proportionate the growth is benign (condyloma acuminatum); but if the proliferation of the epithelium is greater than the resistance offered to it by the connective tissue, the epithelial cells penetrate the lymph spaces of the latter and we have the beginning of carcinoma.

The incentive to such a proliferation of the epithelium is analogous to the procreative activity that is observed in the lower forms of life when they are exposed to difficult conditions of growth. For example, a destruction of some of the epithelial cells upon a surface, results in an increased activity of those remaining in an endeavor to replace the defect. Through repeated insults, which result each time in proliferation of the epithelium, a condition is finally reached, in which, from the more or less continual irritation, the cells take on an abnormal activity of growth. In this light, carcinomas cannot be looked upon as infectious growths; they are rather the result of repeated epithelial insults produced by chemic or mechanical means, and perhaps, indeed, the irritative action of microorganisms.

Although the etiology of carcinoma is not plain, Israel's views seem to be well founded. The manifest relation between cervical injuries and carcinoma need not be discussed. As for the parasitic nature of carcinoma, the burden of proof still rests with those who would account for it in this way.

Recognition of the earliest epithelial invasions in carcinoma, involving as it does histologic elements in histologic proportions, depends, I believe, upon histologic methods.

It has been repeatedly urged that carcinoma of the cervix may as well be recognized by clinical means as by histologic examination of excised tissue from the cervix. It is true that in advanced cases the microscope usually but serves the purpose of confirming the clinical diagnosis. During the past 3 years in Dr. Clark's service at the University Hospital, the diagnosis of cervical carcinoma has never been made by histologic methods alone. In every case sections were taken and an examination made. This served to confirm the clinical diagnosis in well-marked cases, or in strongly suspected ones settled the question one way or the other. This histologic examination has several times prevented hysterectomy that would have been considered advisable in the absence of the help afforded by the microscope.

In no case, however, in which the clinical diagnosis was carcinoma has the histologic examination failed to agree. And in no case, so far, has the microscope discovered carcinoma of the cervix where it was unsuspected. But it must be remembered that cases which find their way to the wards of a hospital are usually advanced cases. Kundrat's percentage of 40 must be looked upon as high. Furthermore, hospital cases usually fall into the hands of men who have had abundant opportunity in the differential diagnosis between benign and malignant affections of the cervix. One who is thoroughly familiar with the disease can diagnose carcinoma about as well by clinical means alone as the physician can recognize tuberculosis. A mistake in diagnosis by clinical means alone would doubtless be infrequent if all women with atypical discharge or hemorrhage could be immediately placed in the hands of a specialist.

With the average physician, who sees comparatively few cases of carcinoma of the cervix in his experience, an early diagnosis must of necessity be many times more or less problematic. It is in such instances that histologic examination would be especially valuable. Outside of large cities there are many difficulties at times in securing the services of a consultant. The patient may feel

indisposed to travel a long distance to have a consultation, and the expense of doing so, together with the objection which most women have to an examination by any other than their own physician, would often, I think, make the physician loath to advise this course strongly unless he was nearly certain of his diagnosis. Curetage and excision of portions of cervical tissue in such cases could be readily undertaken and the specimens submitted to a competent pathologist. In this way many cases of cervical carcinoma would be discovered in their incipency. What has been said about my own experience with cases of Dr. Clark at the University Hospital, of cervical carcinoma, in no way casts doubt upon the value of the microscope. We unfortunately do not see these patients as a rule early enough to make the diagnosis entirely by histologic means.

In carcinoma of the fundus there is a somewhat different problem. Here the parts are less accessible to the finger and to the eye. Many have argued that even here carcinoma gives indubitable clinical signs which are sufficient for a diagnosis. In a large proportion of cases this is true. But, on the other hand, there are many times when a benign condition may so closely resemble carcinoma as to be subjected needlessly to a radical operation, and there are cases of early carcinoma of the fundus which would never be diagnosed by clinical means alone.

In a previous paper⁶ I reported 2 cases in which, although the physical signs pointed to carcinoma, microscopic examination of sections from the cervix and particles cureted from the uterus showed their benign nature. Without the assurance given by the microscope in these cases, the clinician would not have been justified in refusing to perform hysterectomy. One cannot afford to temporize in suspected cases. The diagnosis must be made at once. How often carcinoma has become hopelessly incurable while the effect of palliative treatment was being observed in an effort to establish the diagnosis! A case of Dr. Clark furnishes a very instructive example of a diagnosis made upon the histologic examination of scrapings from the uterus. The clinical symptoms were not only negative, but indeed, strongly indicated a benign process:

The patient, a single woman, aged 53, had complained for nearly a year of profuse bleeding at the time of her menstrual periods, which were undergoing the irregularity characteristic of the menopause. Pelvic examination showed a virginal condition of the external genitalia and cervix. The uterus was small, even rather undersized, and the adnexa were normal. Curetment was performed and the scrapings examined as a part of the regular routine following all curetments. I found in these scrapings an adenoma malignum beginning to undergo carcinomatous degeneration. The report was sent to Dr. Clark, who had some difficulty in convincing the family that hysterectomy was necessary. The case had seemed so undoubtedly benign at the time of the curetage that they had been assured that no further treatment would be required. Under some lingering doubt hysterectomy was performed. Even after removal of the organ there was not the slightest indication that it was the seat of a malignant growth. A small fibroid nodule was found embedded in the cervical wall, and this was enough to explain the metrorrhagia. After the uterus had been opened, however, there was no doubt as to the correctness of the histologic diagnosis.

One such case as this justifies the routine histologic examination of cervical tissue or curetings in the face of a hundred cases in which such an examination proves unnecessary. Bearing these facts in mind, the physician should employ the microscope in all cases of metrorrhagia in which the diagnosis is not entirely plain. After every amputation of the cervical lips, the excised tissue should be routinely examined to detect whether a malignant has been mistaken for a benign process. In cases strongly suspicious of carcinoma, a positive diagnosis can be made while the patient is under ether; so that if a malignant growth is found, hysterectomy may be immediately undertaken. Suitable sections for diagnosis can be prepared in 15 minutes by means of a freezing microtome. It should be remembered that the

cervical tissue excised for diagnosis ought to be a section through the entire suspected area; diagnostic curetage must include every part of the endometrium. Many times a failure of the microscope in these cases can be attributed to insufficient material.

Excised portions of the cervix or curetted particles of endometrium should be placed for preservation in 4% formalin; tissues improperly preserved are also unsuitable for a positive histologic diagnosis.

Winter⁷ recently estimated the percentage of cases coming to his clinic in which the disease had not invaded the parametrium. In 240 cases, he believes 40% were operable in the sense in which the term has been employed in this paper. He believes every case would be operable if it was taken at the first onset of symptoms. In order to increase the percentage of operability he advocates calling the attention of physicians and midwives to the proper course in every suspicious case. Every physician should be urged to pay the closest attention to any suspicious symptoms occurring in the child-bearing woman about the menopause, and to take every means at his command to determine at once if there is any possibility of malignant disease.

FACIAL PARALYSIS.¹

BY

NORTON L. WILSON, M.D.,

of Elizabeth, N. J.

Ophthalmologist, Otolologist, and Laryngologist to the Elizabeth General Hospital, etc.

The subject of facial paralysis has been chosen for consideration because it is one which interests not only the otologist, but the general practitioner as well.

To Sir Charles Bell we owe the discovery that in the nerve trunks there are special sensory filaments which serve to transmit impressions from the periphery of the body to the sensorium, and special motor filaments which convey motor impressions from the brain or other nerve centers to the muscles. He showed that no motor nerve ever passed through a ganglion, and likewise demonstrated, both from theoretic considerations and actual experiment on living animals, that the anterior roots of the spinal nerves were motor and the posterior roots sensory in their functions.

His discoveries have been regarded as the greatest since the time of Harvey. Following is an excerpt from a paper on the nerves of the face, read by him before the Royal Society, July 12, 1821:

The nerves of the face are first the trigeminus, or fifth, of Willis, and that familiarly called the portio dura of the seventh, but which in this paper will be called the respiratory nerve of the face.

If an ass be thrown and its nostrils confined for a few seconds, so as to make it pant and forcibly dilate the nostrils at each inspiration, and if the portio dura be now divided on one side of the head, the motion of the nostril of the same side will instantly cease, while the other nostril will continue to expand and contract in unison with the motion of the chest.

On the division of the nerve the animal will give no sign of pain, while touching the superior maxillary branch of the fifth nerve gives acute pain.

This experiment proved conclusively that the seventh nerve was the motor nerve, and the fifth nerve was the sensory nerve of the face. It also afforded a reason for calling it the respiratory nerve of the face, as it controlled the motions of the nostril.

It is to this illustrious physician that gratitude is due for showing that all cases of facial paralysis are not due to intracranial lesions.

He related the case of a lady who, in the eighth month of pregnancy, suffered from partial paralysis of the muscles on one side of her face, due to the action of mercury in her mouth. The sore mouth, which caused inflammation of a lymphatic gland between the mastoid process and the angle of the jaw, compressed a branch of the seventh pair of nerves.

We thus see that early in the last century, Dr. Charles Bell actually described palsy of the facial nerve. To what he discovered and described, little has since been added. The facial nerve has its origin in the floor of the fourth ventricle, its fibers wind around the nucleus of the sixth cranial nerve, and it emerges from the medulla between the olivary and restiform bodies. It then travels side by side with the auditory nerve, passing forward and outward across the base of the brain, and enters the internal auditory meatus. Within the meatus it lies on the inner side of the auditory, and as it approaches the bottom of the meatus it is found directly over the eighth nerve. Here the auditory nerve divides into two branches, one going to the cochlea, the other to the vestibule, while the facial nerve enters the aqueduct of fallopius, crosses the upper part of the cochlea, and bears downward and backward. It is at this point that we find the geniculate ganglion. This is a small oblong enlargement or knot. Until recently this ganglion has been described by anatomists as belonging to the seventh nerve. It is now almost definitely settled that it belongs to the pars intermedia of Wrisberg. As to the function and origin of the pars intermedia, there is much uncertainty and contrary opinion.

Gray says it may be regarded as the sensory root of the facial nerve analogous to the superior root of the fifth. Its root would be the geniculate ganglion.

Allen says it is remarkable for not involving all the fibers of the facial and for receiving the terminal fibers of the pars intermedia. Bigelow believes that the chorda tympani is a continuation of the nerve of Wrisberg and Sapolini calls it the thirteenth cranial nerve and ascribes to it a function concerned in the power of speech.

Deaver says "the seventh nerve arises as two portions, the pars intermedia of Wrisberg arises deeply from the forepart of the nucleus of the ninth cranial nerve. It is considered a portion of the glossopharyngeal nerve. The facial nerve proper has its origin in the floor of the fourth ventricle." It is evident from Deaver's description of the nerve that he is uncertain about the pars intermedia and that he is not ready to declare whether it is a part of the seventh or of the ninth. If the facial nerve is purely a motor nerve we do not understand why it should have a ganglion. Sir Charles Bell demonstrated that no motor nerve passed through a ganglion. We therefore think it safe to conclude that this ganglion belongs to the pars intermedia which is a true sensory nerve, that the nerve just described by Deaver as a portion of the seventh or ninth, is nothing more or less than the dendrites of the geniculate ganglion going back to the brain and that all the so-called sensory filaments of the facial nerve terminate in the geniculate ganglion and are not branches of the facial nerve itself.

Let me further call attention to the fact that the facial nerve passes backward from the ganglion above the fenestrum ovale for about one centimeter, then turns downward for 12 mm. or 14 mm. where it emerges from the stylomastoid foramen, here to spread itself out to supply the muscles of expression of the face, the auricle, the stylohyoid, the posterior belly of the digastric and the postauricular space.

Most anatomists say that there are connecting twigs between the auditory and facial nerves in the internal

¹ Read before the Clinical Society, March 17, 1903.

auditory meatus. I have seen these twigs, but I believe they connect the auditory nerve with the pars intermedia and not the facial nerve with the auditory. Secretory branches are received from the parotid and submaxillary glands into the ganglion, but here again I cannot share the opinion that they come from the facial nerve, although efferent fibers may be secretory. I incline to the belief that these glands are stimulated through the nerve of Wrisberg, which is so intimately connected with the facial nerve as to be involved when ever the seventh nerve is injured in the aqueductus fallopian.

The 3 petrosal nerves which are said to arise from the geniculate ganglion are sensory filaments going to the ganglion. The first branch of the facial nerve is the stapedius; this supplies the stapedius muscle, which is inserted in the neck of the stapes and raises its forepart, thus compressing the contents of the vestibule.

The so-called second branch of the facial is a twig to the pneumogastric nerve, which apparently comes off the facial trunk just above the chorda tympani. This, like the other filaments to the ganglion, is sensory, and undoubtedly goes to the geniculate ganglion, being a part of the pars intermedia.

The chorda tympani is considered the last branch of the facial in the fallopian canal, but it is nothing more or less than a continuation of the pars intermedia; it supplies the anterior two-thirds of the tongue with taste.

From the foregoing description it is to be gathered that there is but one branch in the facial canal which actually comes directly from the facial nerve, and this is the stapedius. The other branches are all sensory, and probably are a part of the pars intermedia. It is impossible to injure one of these branches in the facial canal without involving the others, and therefore from a clinical standpoint the distinction which has been drawn is of no practical value.

Morbid Anatomy.—The view held by many writers that paralysis of the facial nerve is an interstitial neuritis with swelling of the sheath of the nerve and compression of the nerve elements, is purely hypothetical. The fact is, that Markowskie found true degenerative neuritis in a case of Bell's palsy. True interstitial neuritis is rare, and in the light of modern pathology we should not designate it as neuritis, but rather as a degeneration of the nerve.

Etiology.—Facial paralysis may arise from (1) a lesion of the cortex, which includes the internal capsule in connection with cerebral hemorrhage, softening, tumors or abscess of the brain; (2) from the effect of toxins of infectious diseases, particularly those of diphtheria; (3) from lesions in the nerve between the pons and the entrance into the facial canal, due to gummatous or other tumors, meningitis, or fractures at the base; (4) from lesions in the aqueductus fallopian due to surgical operations upon the mastoid or middle ear, otitis media or caries in the middle ear, or fractures of the petrous portion of the temporal bone may cause this form of paralysis; (5) from lesions in the peripheral portion of the nerve, external to the stylomastoid foramen due to mumps or lymphatic enlargement; pressure from obstetric forceps, or the action of cold wind blowing upon the face.

Roulland¹ reported several cases not due to forceps. In these cases the pressure is believed to be exerted from the promontory of the sacrum and superior strait, or by the ischium at the inferior strait, if the head is long arrested at one of these points. Facial paralysis has not been observed with face or breech presentations. Otitis media, and especially the chronic form is a frequent cause in children. I was under the impression until I began to prepare this paper, that otitis media furnished a large percentage of the cases, but I am forced to admit after looking over the histories of those coming under

my personal observation, and those of others, that only a small percentage of these cases (about 8%) are due to this cause.

In the majority of cases, facial paralysis is due to cold wind striking the face; such cases are called rheumatic neuritis, although Reiks¹ believes them to be due to catarrhal conditions of the middle ear.

Syphilis is rarely responsible outside the cranial cavity.

Hare says facial paralysis may result from hysteria, but, of course, it would be associated with other symptoms of hysteria.

It may also come from locomotor ataxia with a lesion in the pons.

It is hardly necessary for me to give a description of the symptoms, as all are familiar with the drawn face on the well side and the smooth face on the paralyzed side.

The diagnosis or location of the lesion is, however, important, as the prognosis depends upon its location. If the lesion is external to the stylomastoid foramen, we have complete paralysis of the facial muscles, involving the orbicularis and frontalis. The sense of taste and hearing remain normal. This is Bell's palsy.

If the lesion occurs within the lower part of the facial canal, we have complete paralysis of the face as before. In addition, however, we have loss of sense of taste in the anterior two-thirds of the tongue on the paralyzed side and a diminished secretion of saliva. The sense of hearing remains normal. This lesion involves the chorda tympani and twig from the glossopharyngeal nerve.

If the lesion is in the upper part of the facial canal, so that the stapedius is involved, and not the ganglion, we have all the last-named phenomena, and in addition, there will be found abnormal acuteness of hearing as the stapedius muscle is cut off, and the tensor tympani has its own way, and makes the drumhead tense.

Nearly all the authors to whose writings I have had access, in speaking of the paralysis of the soft palate, attribute it to the involvement of the superficial petrosal assuming that this nerve comes from the geniculate ganglion. In this assumption I cannot concur, because these filaments, in my judgment, are sensory, and not motor in their character. It is the fifth nerve which innervates the soft palate, and is the one involved when the palate is paralyzed.

As confirming my contention, I desire to report the following case:

John P., aged 39. Previous history good. He fell from a bridge to the street, a distance of about 18 feet, was picked up unconscious and taken to a hospital. He bled from both ears for 2 days. It was noticed that he was totally deaf, and that the left side of his face was paralyzed. The tuning fork placed upon his skull proved him totally deaf. He complained of tinnitus and vertigo. There was a fracture at the base of the skull involving both eighth nerves and the seventh nerve of the left side. The patient had no sense of taste in the anterior two-thirds of the tongue on the left side. The uvula and the soft palate were normal, and salivary secretion was apparently diminished on the left side. There was a scar about 2 inches long over the left mastoid process. Contractility of the muscles of the left side of the face was lost for the faradic current, but was apparently increased for the galvanic current.

If the geniculate ganglion was affected and the contention of writers is correct, the soft palate would be involved, but in this case the palate was normal.

If the lesion is in the nucleus, there is no disturbance of taste. This fact seems to prove that the chorda tympani is the nerve of taste. It proves further, that it is not a branch of the facial nerve, but is a continuation of the pars intermedia. In nuclear or infranuclear lesions the reflexes are lost, reactions of degeneration are present, and paralysis of the sixth nerve. If the lesion occurs in the cortex, the muscles of the lower half of the face are paralyzed, while the secretion of saliva and the

¹ Holt, p. 108.

¹ Johns Hopkins Bulletin, April, 1902.

sense of taste remain normal, because they are not innervated by the facial, but are controlled by the pars intermedia. The orbicularis and forehead muscles are intact, the patient being able to close the eye-lid. These muscles are innervated by the upper branch of the facial nerve. This feature, together with the normal electric excitability, points to a supranuclear lesion. The involvement of the lower half of the face is due to the fact that only the inferior or face branches of the facial nerve receive exclusively crossed innervation, while the upper branch, which supplies the orbicularis and frontalis and motor trigeminus is innervated from both hemispheres, so that a defect in one may be equalized by the other. That the upper and lower branches of the facial nerve have separate nuclei, has not been as yet anatomically proved. That they are, however, functionally distinct is further shown by the fact that in bulbar paralysis, a disease of the nerve nuclei of the medulla, only the inferior facial nerve is involved.

Church and Peterson say, "the nucleus of the seventh nerve receives fibers from the oculomotor nucleus which go to the orbicular muscles of the eye-lid."

These hypotheses do not explain the fact that the secretory and gustatory functions escape involvement.

It seems to me the explanation is to be found in the fact that they are branches of the pars intermedia, and not branches of the facial nerve.

In cortical lesions we also have the arm and leg of the same side involved, hence it is not difficult to locate a cortical lesion.

Facial paralysis with arm paralysis of the same side, followed in a short time by paralysis of the leg of the opposite side, is quite characteristic of syphilitic arteritis at the base of the brain.

When we find facial paralysis on one side and arm and leg of the other side, the lesion is in the pons above the decussation of the pyramid and below the facial fibers.

I recall a case in which a boy had facial paralysis of the right side, followed in a day by paralysis of the right arm and on the next morning by an involvement of the right leg. The case was one of thrombosis in the right lateral sinus due to middle-ear disease. At the autopsy an abscess in the left temporosphenoidal lobe was found, due to infection by the streptococcus.

After a diagnosis has been made and the lesion located, what should be done for the patient?

We must remember that electric changes soon develop in paralyzed muscles. The reaction of degeneration, partial or complete, appears in 4 or 5 days after the paralysis occurs.

According to Starr:

The electric contractility in the facial muscles is usually altered. In some cases the faradic contractility is preserved and the galvanic contractility is slightly increased, so that the muscles respond to a weaker current than those upon the normal side. In these cases, recovery occurs within 3 or 4 weeks.

In cases of medium severity however, there is a partial reaction of degeneration. The faradic contractility is very much diminished, or even lost, while the galvanic contractility is heightened, so that only a weak current is necessary to produce contractility. In severe and permanent cases there is a total reaction of degeneration, a complete loss of faradic contractility, and a gradual reduction in the galvanic contractility.

One can readily see how important are the electric reactions, not only as symptoms, but as prognostic indications.

Electricity should not be applied, therefore, until the end of the third week, except to ascertain the excitability of the muscles. One month after the paralysis has occurred, electricity and massage should be used regularly and systematically. If the muscles respond to faradism, that current should be used. If they do not respond to the induced current, galvanism should be used, and should be used only with the galvanometer, so that the strength of the current may be known and gradually increased, if necessary.

Flannel wrung out of hot water, or the hot water bag applied to the side of the face for the first 4 days does something toward relieving the stiffness of the muscles and dilating the vessels, thus favoring the process of degeneration and regeneration. Blisters over the mastoid, in my opinion, do more harm than good, except for their mental effect.

Endeavor to ascertain the cause, and if due to ear trouble, remove the cause. If syphilis is suspected, potassium iodid and mercury should be given in full doses.

The eye must be protected by hanging a patch over it, or by the wearing of colored glasses. It must be kept clean by washing with a solution of boric acid. Internal medication is of little or no value.

DRAINAGE OF THE CHEST IN EMPYEMA.¹

BY

LEON BRINKMAN, M.D.,
of Philadelphia.

I have selected the subject of "Drainage of the Chest in Empyema" with the hope that interest may be more thoroughly aroused in the improvement of the technic of surgery of the chest, which has not kept pace with surgery in other lines. It is true that the immediate performance of the operation for empyema, is not so brilliant as operations done for abdominal and pelvic disease, nevertheless the immediate and remote effects on the patient, obtained by the method I shall describe, are so patent, that I trust a more universal adoption of the method will be assured.

In considering the subject of pleural effusions, one must think of the degree of pleurisy which preceded. It is certain that before suppuration took place there must have been inflammatory changes in the serous membrane lining the chest wall. For a fair presentation of the subject, which is a complication, we must consider the etiology of pleurisy. The frequency of purulent pleurisy should not be underestimated. According to the records of St. Bartholomew's Hospital, London, for 10 years (1884-1893), the number of patients treated for pleurisy, in whom the pleurisy was the main and foremost disease, and not secondary to any other disease of a less serious nature, was 867; of these, 620 were males, and 247 females. Of the 867 cases 216 were purulent pleurisy, almost 25%, and of the empyemas 85 cases were in children, under 10 years of age, or 39.3%.

Purulent pleurisy is a secondary disease, rarely primary, and occurs as a sequel to serofibrinous pleurisy, to various infectious diseases, scarlet fever, measles, whoopingcough, pneumonia, enteric fever and tuberculosis; also the infections following traumatism either from a punctured wound of the pleura, from a fractured rib or from a penetrating wound.

The types of the infecting agent vary bacteriologically; the pneumococcus, streptococcus, and the tubercle bacillus have been found. Flexner,² in a study of 11 cases of acute pleurisy as terminal infections, found that the streptococcus was the infecting agent in 4 cases, *Micrococcus lanceolatus* in 2, *B. coli communis* in 1, *B. proteus* in 1, streptococcus, staphylococcus and bacillus in 1, *B. aerogenes capsulatus* and *B. coli communis* in 1, and *B. coli communis* and an unidentified bacillus in 1. He also found the infection gained entrance through the peritoneum in 4 cases; intestine in 3, bronchitis 1, infarction of lung 1, and doubtful 2.

The prognosis of purulent pleurisy depends upon the character of the infecting agent and the primary disease. From its very nature the tuberculous variety would not present a favorable outlook, yet in a small percentage of cases recovery does occur. A streptococcus infection and

¹ Read by invitation before the Philadelphia Academy of Surgery, and the Burlington County Medical Society.

² Journal of Experimental Medicine, Vol. i.

empyema from gangrene of the lung may in some instances result in cure, if early surgical interference is instituted. There is no case of empyema too desperate to prevent the attempt at evacuation and drainage. In performing this procedure, the most rigid asepsis should be observed, in order that an additional infection of the pleural cavity will be avoided.

In order to avoid clogging of the needle in the exploratory puncture, I would suggest from experience that it would be wise to have the barrel of the syringe half filled with warm sterile saline solution, which can be expelled into the chest cavity before aspiration is begun. As a further means to avoid infection, it is a good precautionary measure to make a small incision under local anesthesia, so as to preclude infection of the needle while being pushed through the skin. Treatment in the past has been limited to aspiration, aspiration with irrigation, permanent aspiration, simple incision, resection, and the Estlander excision.

Aspiration as a surgical measure should be condemned, except as a means of arriving at a diagnosis or when the amount of purulent secretion is too extensive to make a radical procedure a safe measure. In the latter instance, the radical operation should be performed some hours after aspiration, so that a fatal syncope may be avoided.

Aspiration and irrigation are open to a much greater objection than simple aspiration, due to the introduction of an irrigating fluid. I shall speak later of the dangers attending irrigation.

Permanent aspiration is probably the least objectionable form of palliative treatment, although even this has many features to condemn it. The fluid withdrawn from the chest by this method must not contain any cheesy masses or loose flakes of fibrin, otherwise there is a stoppage in the tube and failure to perform its function; ulceration occurs around the tube or canula, and the entrance of air follows, one of the things which should be avoided; again, it is not a practical procedure for private practice, as a constant supervision is necessary to prevent infection through the tube. Simple incision for drainage, like the preceding measure, is well enough as a temporary means in the treatment of empyema, but it is a failure as a curative measure, as the incision ceases to perform its function after a short period of time.

Until a comparatively recent date, simple excision of the ribs and the introduction of tubular drainage has been the ideal means of surgical treatment of empyema. There is no doubt that this affords a very excellent means of disposing of the purulent accumulation but, like the measures spoken of previously, some strong arguments may be urged against it: (1) It does not dispense with a foreign body in the chest; (2) the tube acting as a foreign body is a continual source of irritation, and adds a factor in the continuance of the discharge; (3) the tube may slip into the chest, and its disappearance remain unaccounted for. I operated upon a patient in which this occurred, and recovered 2 pieces of drainage-tube. This patient had been operated upon twice before.

The necessity for extensive excision in children will depend upon the amount of lung involvement by adhesion and fixation in the upper portion of the chest cavity. As a rule, excision of 1 or 2 ribs will suffice if done early before adhesions have formed; if, however, these are present, 3 or 4 ribs may have to be divided, in order to allow sufficient space for the manipulation necessary to free the lung and permit it to expand.

The question as to the proper anesthetic to select in operations for empyema is a delicate one to decide. In 27 cases in which operation was done by the improved method ether was administered in 6, and chloroform in 21. In my opinion, chloroform is the ideal anesthetic provided the heart is in good condition and not too much displaced, and it is especially indicated in children. The advantages it possesses over ether are the avoidance of

the laryngeal and bronchial irritation, the shortened stage of excitement, and the prevention in a large measure of the usual struggle just prior to complete anesthesia. Ether is a respiratory depressant. If there is a large accumulation in the chest then aspiration should be performed several hours prior to the administration of the anesthetic.

The operation advocated by Estlander, while a distinct advance in the treatment of empyema, is a very extensive one, and does not possess any advantage over the following method. Among the 27 cases in which immediate drainage was instituted there were several in which, had it not been adopted, I would have been compelled to do the Estlander operation, which entails a much greater amount of manipulation, destruction of tissue, and has a greater mortality.

Dr. Carl Beck has devised an operation similar to the one which I advocate, but it differs in several vital points. I was not aware of the method employed by Beck until the September, 1902, meeting of the Pennsylvania State Medical Society, when it was brought to my notice by Dr. Gibbon, of Scranton. Since these facts were brought to my attention, I have carefully gone over the literature, and found that Dr. Beck reported his experience with suture of the pleura to the skin as early as 1894; he, however, introduced tubal drainage after several days to avoid hemorrhage. The operation as recommended by Beck consists in making an incision over and parallel to the rib, reflecting the superficial structures, denuding the rib of its periosteum, introducing a special pair of scissors beneath the rib, which serves the purpose of a periosteal elevator as well, and excising 4 inches of the ribs the pleura is opened in the axis of the wound and stitched to the skin.

The main points of difference between the operation of Beck and the one I am about to describe are: That in the latter, additional facility is afforded to manipulate within the chest cavity; that with each inspiratory movement of the chest wall a wider range of lung expansion is possible; a freer inspection of the chest cavity is permitted, making it easy to avoid the formation of pockets, and doing away with the necessity for packing the chest cavity.

The operation for immediate drainage of the chest for empyema is performed in the following manner:

After the patient is properly prepared, a vertical incision is made in the midaxillary line down to and exposing the fifth, sixth, and seventh ribs, more if necessary. The skin, superficial fascia and muscles are reflected back on either side of the wound, so as to expose at least 2 inches of the ribs; the periosteum is freed from the anterior surface so as to permit the easy introduction of the periosteal elevator beneath the ribs. An elevator is carefully introduced beneath each rib successively, denuding them of their periosteum and underlying structures. The ribs are divided; the pleura is protected from injury by the special elevator, which performs the twofold purpose of freeing the periosteum and elevation and fixation of the ribs, so as to facilitate the division of the bone with cutting forceps.

The pleura having been exposed, a small vertical incision is made in it at the lower angle of the wound, and about the middle of the space previously made, to permit the more gradual escape of the pus. Upon complete evacuation the incision of the pleura is continued upward until it reaches the upper angle of the wound.

A free inspection of the chest cavity is possible by retraction of the wound; if the lung is found bound down and collapsed in the upper portion of the chest cavity, an attempt should be gently made to separate the adhesions; if these are too firm to admit of this, then they must be incised, and blunt dissection resorted to, avoiding unnecessary force, which might produce extensive laceration of the lung tissue.

When the condition within the chest cavity is complicated by encysted pockets of pus, either interlobular or between the lung and the posterior chest wall, it may be necessary to go as high as the third rib in the excision.

The operation is completed by stitching the pleura and skin together around the entire wound, thus offering a large free opening for the escape of the succeeding secretion. In order to avoid injury to the diaphragm, all incision should be made with this organ in view or touch, a finger introduced within the chest cavity acts as a guide, when going below the seventh rib.

Before completing the operation, the periosteum should be carefully dissected away, other wise, during the process of

repair and closure of the wound, masses of fibrous and calcareous tissue are formed.

A serous membrane like the pleura, which under normal conditions has such great absorptive powers, is capable of taking up a toxic amount of drug from any fluid thrown into the chest cavity which would contain a sufficiently strong antiseptic to alter the character of the pus. Although the character of the pleura is changed by the inflammatory process, still it is capable of absorption.

In commenting upon the practice of irrigation of the chest cavity, the dangers of this procedure should be well borne in mind; fatal syncope and hemiplegia are prominent among these. I have found from experience that irrigation of the chest after operation does not diminish the amount of discharge, but rather, on the other hand, favors its increase.

During the past 5½ years I have spent considerable time and thought in perfecting an immediate method for drainage of the chest without tubes, and have had opportunity to compare it with excision and tubular drainage. The total number of patients operated upon for empyema was 47; 20 by excision and tubular drainage, 27 by excision and suture of the pleura to the skin. The results by the immediate method of drainage were so conclusive that I believe the benefits from it are unquestionable. Of the 27 patients treated by this method of drainage, but two had a protracted convalescence, and this would have been the case under any method employed.

The first was a young girl with tuberculous empyema, complicated by an extensive tuberculous involvement of the base of the right lung. It is now 2 years since she was operated upon. Her condition is as follows: A small discharging sinus is seen at the site of the former operation at about the middle of the scar, from which a slight amount of semipurulent secretion makes its escape. Microscopic examination of the discharge from the sinus and of the sputum fails to reveal tubercle bacilli. Her general health has improved in the past 4 months to a remarkable degree, her weight having increased 30 pounds. The area of lung involvement in the impaired lung has decreased to half its former dimensions.

Since this paper was written and at the present time the sinus has closed completely.

The other case also occurred in a young female. The empyema was a secondary complication to pneumonia. In addition to the empyema, there was a localized patch of gangrene of the lung, which upon separation developed into a bronchial fistula. With the gradual decrease in the size of the wound by cicatrization, there has been a perceptible decrease in the amount of discharge, and of the air making its escape through the sinus. At the present time there is scarcely any discharge, and air can only be forced through the sinus when the breath is held and forcible compression of the chest wall made.

This patient is also well at the present writing, the sinus having closed shortly after completion of the article.

The remaining 25 patients operated upon by this method have all made successful recoveries, the shortest time for a cure to be established was 3 weeks, and the longest 5 months.

It will be found necessary in some few cases to freshen the edges of the wound and bring them together with sutures, so as to hasten the closure. This was done in 5 of the 27 cases, the discharge having ceased after 3 weeks.

The breaking up of the adhesion between the lobes of the lung and chest wall so as to allow the lung to expand, in a great measure robs the convalescence of a very distressing complication—the almost constant cough. It also permits the patient a much greater degree of comfort, and the securing of more sleep.

Children Gain Weight Periodically.—Some curious experiments have been made at one of the royal philanthropic institutions in Copenhagen. For some years back the 70 boys and girls in the place have been carefully weighed every day in groups of 15 and under. Thereby it is proved that the children gain weight mostly in autumn and in the early part of December. From that time to the end of April there is scarcely any increase in weight. More remarkable still, there is a diminution till the end of summer.

SPECIAL ARTICLES

MEDICUS ET MEDICA.

BY

HELEN MACMURCHY, M.D.,

of Toronto, Canada.

[Concluded from page 234.]

But to return to the history of the London School of Medicine for Women. The guilds and great companies of the city of London are among its benefactors, but it has never received a subsidy from the government, though it does public work; it can still boast of its poverty, a poverty combined with efficiency.

Since 1881 its students have taken 8 gold medals in medicine from the London University, 3 other students having obtained standing qualifying them for medals; and 2 students have obtained standing qualifying them for medals in the B.Sc. examination, while many stand high in the honors list.

Private munificence has done something for the College, one of its benefactors being Mrs. Oakes, of Paramatta, N. S. W., who gave £4,000. The Pfeiffer bequest made it possible for the trustees to build the new Pfeiffer wing, which was opened in 1898 by the Prince and Princess of Wales. This mark of royal favor, the success of the occasion, and the interest displayed, greatly encouraged the friends of the school, and the whole school is now being rebuilt at a total cost of about £35,000. The administration of the school has always been excellent, so that with all their expansion they have kept out of debt.

It should be remembered that much of the distinction and success of English women physicians is due to the fact that they and their friends founded the "New Hospital" officered entirely by women, and that the work done by the doctors there in advanced surgery, medicine, clinical teaching, and the various departments of specialists' work showed that these higher walks of medicine were not beyond them.

The school has now 200 students, and in its short history there is already something of which to be proud. Not to speak of the living, there were two brilliant students of whom the highest hopes were entertained when, in the glory of their youth, untimely death closed their brilliant careers.

Miss Mabel Webb took her M.B., London, in 1898, and was curator of the Royal Free Hospital Museum at the time of her early death, having devoted her talents to the study of pathology. She was earnest and enthusiastic, and deeply mourned by her friends, who have founded the Mabel Webb Memorial Scholarship for the School. Her mother is rebuilding the museum and laboratories in memory of her gifted daughter, so that the students of the college may be practically acquainted with the methods of modern pathologic research.

Miss E. Helen Prideaux, who took the gold medal and scholarship in anatomy at the University of London in 1881, and was placed in honors in every subject at the M.B. and B.S. examination in 1884, was appointed house surgeon at the Children's Hospital, Paddington. She contracted diphtheria in the discharge of her duty, and after great suffering, borne with the utmost fortitude and heroism, died November 9, 1885. Her ability, her refinement and sympathy, gave promise of great things in her professional career, and her friends have sought to perpetuate her memory in the Helen Prideaux Scholarship.

As has already been stated, the Conjoint Scottish Colleges of Physicians and Surgeons opened their examinations to women in 1886, and then separate medical classes were organized for women in Edinburgh, the Edinburgh School of Medicine for Women being opened in 1887, with 14 students; Leith Hospital being its clinical school. Among the first students of this school was the first Hindu lady who ever studied medicine in Great Britain. The dean of the school was Dr. Sophia Jex-Blake, one of the great pioneers of the movement. She was also the first woman to receive appointment as a lecturer in any British university, being appointed extramural lecturer on midwifery to the University of Edinburgh in 1888. The Edinburgh School

of Medicine for Women remained open till 1898, when the executive committee was reluctantly compelled to close its classes on account of the action of the University Court, which gave the Edinburgh School of Medicine for Women to understand in 1886 that "mixed classes" in medicine were objectionable (and therefore the School of Medicine for Women was a necessity), but in 1898, while stating that they "adhered" to the principle of separate classes, stated also that they "granted permission" for "mixed classes." But the 12 years' record of the Edinburgh School of Medicine for Women is a proud and successful one. Dr. Jex-Blake retired from practice in 1899, after nearly 40 years of work, and is now living in Sussex, England, where she was born. Her great services to the cause for which she made so many sacrifices will not pass unremembered. The farewell reception tendered to her in Edinburgh was attended by rich and poor alike. Edinburgh, where she passed nearly half her life, will never forget her. Her Edinburgh residence, Bruntfield Lodge, is now a woman's hospital, which would have been called after her if she would have permitted it.

The Medical College for Women, Chambers street, Edinburgh, has now been in existence over 10 years. It was founded and is conducted by the Scottish Association for the Medical Education of Women. It has the great advantage of a place of residence for its students, Muir Hall. In its first year its students numbered 9; in 1900 there were 105. The students are admitted to the Royal Infirmary (where 80 beds are reserved for their instruction), the Royal Hospital for Sick Children, and the Royal Maternity Hospital.

Queen Margaret College is the Women's Department of the University of Glasgow founded as the result of a movement for the higher education of women, begun in Glasgow in 1868 by Mrs. Campbell of Tulliechewan. She arranged for courses of lectures for women from Professor Edward Caird and others, and in 1877, at a public meeting, the Glasgow Association for the Higher Education of Women was formed. In 1883 this Association was incorporated as a college, and the college was named after Queen Margaret, wife of Malcolm Canmore, the first Scotch patroness of the Liberal Arts.

In the same year Mrs. John Elder of Govan, widow of the great ship-builder and engineer, presented to the college the buildings and grounds now occupied by it on condition that £20,000 should be raised as an endowment fund. This condition was fully met by the endowment fund collected and presented by Mrs. Campbell, amounting to over £25,000. In 1893 the College Council having regard to Ordinance No. 18 of the Universities' Commissioners, transferred to the University of Glasgow their endowment funds, and, with the concurrence of Mrs. Elder, the buildings and grounds, which had cost over £15,000. There were 52 students of Queen Margaret College who took the degree of M.D., and it is interesting to add that the founders of the college, Mrs. Elder of Govan and Mrs. Campbell of Tulliechewan received the honorary degree of LL.D. at the recent celebration of the Ninth Jubilee of the University of Glasgow, being the first women to receive that honor.

Among other institutions now making provision for the medical education of women may be mentioned the University of Aberdeen, the University of Durham, and the University of St. Andrew's. At St. Andrew's the munificence of the late Lord Rector, the Marquis of Bute, enabled the University to erect separate practical anatomy rooms for men and women students, and the late Dr. W. T. Thomson founded 14 annual bursaries, for the express purpose of furthering the medical education of women.

In Great Britain over 100 poor law, asylum, and hospital appointments are held by women physicians. A woman physician is on the medical faculty of Birmingham University, another on that of the University of St. Andrew's, and a third is examiner in midwifery of the Royal Colleges of Ireland.

Women physicians are lecturers or examiners to the County Councils of London, Westmoreland, and Montgomery; medical officers, lecturers or examiners to the school boards of London, Edinburgh, Nottingham and Sheffield. They are also medical officers to the general postoffices of London, Liverpool and Manchester; medical referees and examiners to insurance companies, etc. The North London Collegiate School for Girls,

the Maria Grey Training College, the Manchester Industrial School, Clapham High School, St. Mary's College, Paddington, Central High School of Newcastle, Wycombe Abbey School, and others have women physicians as consulting or resident physicians.

Another recent appointment is that of the Hon. Ella Scarlett, M.D., daughter of the late General Lord Abinger, and formerly court physician to the Emperor of Corea, as medical officer to the Refugee camps for Boer women and children. Several women physicians have been in the Indian Medical Service, and also on plague duty in India and Egypt. Many women physicians are members of the British Medical Association and other medical societies. At the meeting of the Edinburgh Obstetrical Society, held January 9, 1901, R. M. Milne-Murray, M.D., in the chair, it was resolved, *nemine contradicente*, that women should now be admitted to the fellowship of the society.

The first woman physician in Canada was Dr. Emily Howard Stowe, of Toronto, who graduated in New York, in 1867. The Woman's Medical College, Toronto, was founded in 1883, by Dr. Michael Barrett, assisted by Mr. James Beatty, Q.C., M.P., and others, especially by the following members of the profession: Dr. George Wright, Mr. Irving H. Cameron, Dr. A. H. Wright, Dr. McPhedran, Dr. Reeve (now dean of the Faculty of Medicine of Toronto University); Dr. Nevitt (now dean of the Woman's Medical College); Dr. Wishart, and Dr. Augusta Stowe Gullen (who was the first woman to take a medical degree in Canada, graduating from Victoria University, Cobourg, in 1883).

Dr. Barrett, first dean of the college, was a just and kind man. He, and all the other members of the faculty and their successors, have, with the chivalry and generosity characteristic of the noble profession to which they belong, carried the college through all these years—years of toil and self-sacrifice never mentioned by themselves, and almost unknown to others.

The examinations and degrees of Canadian universities are all open to women, and women have studied medicine at Queen's University, Kingston, the University of Manitoba, Winnipeg, and Dalhousie University, Halifax. The Woman's Medical College at Toronto is the only medical college for women in Canada, and has had over 80 graduates.

In 1867 the first medical school for native women in India was started at Bareilly by Surgeon Corbyn, and in 1875 the Madras Medical College was opened to women. The natives of India themselves really began this movement, and in 1883, by the munificence of a Parsee gentleman, the Kama Hospital (named after the founder) was established. It is now one of the hospitals of the Indian Medical Service, and a dispensary in connection with it was established by the liberality of a Mussulman. Her Majesty Queen Victoria took a deep personal interest in this movement, and the kind Countess of Dufferin, as all the world knows, was the life of it in later years, so that in 1888 there were 30 hospitals in India entirely under the charge of women physicians, and in 1896 the number had grown to 133, and in 1900 there were 247 hospitals, dispensaries, etc., many of them in connection with Christian missions where 1,667,329 women patients were treated by women physicians.

The first woman to receive the Doctor's degree in Germany was Dorothea Erxleben (nee Laporin), and the date was June 12, 1754. Her father, a physician, educated her and encouraged her to aspire to a Doctor's degree; her brother's schoolmaster, Rector Eckhard, taught her Latin, and predicted that in her the Muses would have one whom they could recognize and proclaim as "an ornament of her sex and theirs." In November, 1741, her father did Frederick the Great a service, and the King at his request undertook to recommend her to the Medical Faculty at Halle, as soon as she thought fit to remind him of this promise. But Dorothea loved the young minister of the Church of St. Nicholas in her native town, married him, and in the next thirteen years discharged faithfully the duties of a wife and mother, caring for her four children, nursing her husband through a long illness, passing through the great bereavement of her father's death, but never quite forsaking the profession she loved. At the age of 39 she reminded Frederick the Great of

his offer, and the King kept his word, and ordered the Faculty at Halle to admit her to examination forthwith.

"For two whole hours," writes the Dean, "Frau Erxleben stood alone, exposed to the questions of the examiners, which she received with admirable modesty and cheerfulness, answering fully and distinctly, solving doubtful matters with extreme skill, and using so free and sweet sounding a Latinity that we seemed to be listening to some matron from old Latium speaking in her native tongue." Deduct a little for the politeness of a Dean—the Dean of a Medical Faculty—and the fact remains that her examiners could raise no objection to her claim on the score of proficiency. Nevertheless they hesitated to go further with the business, and, after consultation, decided to report progress to the King. "Frau Erxleben," said the examiners, "has passed her examination well, and shown herself a man" ("optime in examine steterit et virum se præstiterit"), but Frederick the Great summarily ordered that the degree should be bestowed. The doctor practised her profession till her death in 1762. Her husband became a Dean and two of her sons rose to eminence.

There are now 406 women engaged in studying medicine in different places in Germany, but their position has heretofore been a difficult one, as they have only been allowed to attend lectures under special conditions. In April, 1901, two ladies passed the German State examination for medical practitioners in Freiburg, Baden, both obtaining the mark "very good." These are, it is stated, the first ladies to qualify in the ordinary way in the German Empire.¹

There are 700 women physicians in Russia. Many of them hold government appointments and are eligible for pensions. The Poor Law Service, the County and City Medical Service, and the Municipal Ambulance Service all have some women physicians on their staff.

The first woman physician in France, Madeline Bres, graduated in 1875, and now there are 85 women physicians practising there, 71 of them being in Paris. In Austria women were allowed to begin the study of medicine in 1897, and in 1898, 50 women had taken advantage of this permission.

There are 20 women physicians in Italy, one of them physician to the Queen, and there is a number in Sweden, Switzerland, Holland, Norway, Denmark, Finland, Roumania, Greece, Portugal. A Swiss lady is court physician to the Emperor of Abyssinia, and an English lady court physician to the Emperor of Corea. There are two women physicians in Egypt, a number in Persia, and also in Turkey. Several have graduated from the University of Mexico, and in Colombia, in Chili, and in Peru, women have begun the practice of medicine.

Nor have the labors of women physicians been without praise and reward.

The Bishop of Stepney, preaching the sermon of the Anniversary Festival Service of the Guild of St. Luke, in St. Paul's Cathedral, October 19, 1899, before the Lord Mayor of London and the sheriffs, who attended in state, together with the chief officers and many members of the Corporation of the City of London, and before a large congregation of doctors in academic costume, took for his text the words, "Jesus went about . . . healing every sickness and every disease," and remarked in the course of his sermon that he welcomed the presence of ladies among the medical graduates; their sympathy with suffering and their ability to commune more freely with some patients than men could, gave them a special mission.

The *British Medical Journal* (June 2, 1900) says: "The West Ham Board of Guardians are advertising for a female assistant medical officer for their workhouse and schools. This is said to be the first time that a lady has been advertised for in this capacity. Other Boards have merely signified that women were eligible. The new departure may be taken as proving that in the other poor law appointments which women have held, they have done well."

The secretary of the Melbourne Hospital, Australia, stated that the two women physicians who were the first to hold appointments on the resident medical staff of that hospital "carried out the duties of their office with much credit to themselves and to the benefit of the charity."

The medical superintendent of one of the largest London infirmaries says: "All the lady assistants I have worked with have been a great success."

In the last New Year's Honors List for India there were but five rewards bestowed on plague medical officers, and one—the Kaiser-i-Hind silver medal—was given to Miss Alice Cathorn, M.B. The same reward was bestowed in May, 1900, on Miss Adams, M.D., of Jodhpore; Mrs. Smith, M.D., of Jullemder, and Miss Campbell, L.R.C.P. and S., of the U. P. Church of Scotland, Ajmere.

One of the first decorations bestowed by His Majesty King Edward was the Royal Red Cross given to Miss L. Emma V. Saville, M.D., of the London Mission, for services at the International Hospital during the memorable siege of the Legations at Peking.

"The two crying evils of our time are the overcrowding of the profession and its decadence in scholarship. This defect of scholarship is associated with, and to my mind, too often begets defect of manners; and the courtesy and old-time courtliness of professional intercourse is rapidly disappearing."¹

These words it were well if men and women entering the medical profession, as well as those responsible for advising and preparing them to enter it, bore in mind. Overcrowding the profession—defect of scholarship—defect of manners. The entrance of women into the profession will have a tendency to increase the first, and it is our duty, as members of the profession, to watch jealously our own professional ethics that no low commercial standards or methods may increase this evil or taint our relations with our patients or with other members of the profession. It is the best return in our power for all that the profession has done for us to make ourselves as worthy members of it as we can be—to love and encourage learning, to prize scholarship, to think as little as possible of our rights and the duties of others to us, while we constantly consider the rights of others and the duties we owe to them, and sedulously cultivate that excellence of character and that beauty and dignity of manner and bearing by which we can best ornament our profession. There are in true womanhood, as in true manhood, some special privileges and endowments which are our share of the perfection of humanity. Let us take these with us when we enter professional life that we may enrich and not impoverish our calling.

The doctors of Queen Anne's time reminded Addison of the British army against which Cæsar fought in 55 B.C. "Some slay in chariots and some on foot."

There are many kinds of success, the making of a professional income sufficient to drive a chariot not being the highest kind. Still, it is not to be despised, and it has been honorably attained by women physicians in London, New York, Philadelphia, and elsewhere.

To do the thing that is right, to enlarge (if so great a thing lie in our power) the boundaries of the kingdom of knowledge, or to help some one else to do so, to win that confidence that comes with power over disease and its evil effects, to know the happiness of making others well and happy, to grow greater in heart and soul and power of service by means of our work and the personal relations which it brings and to do that work from pure motives and with a constant memory of the high references of life—these are the better part of professional success.

Typhoid Fever in Germany.—Thanks to the improvements in the public sanitation in many large German cities in which formerly numerous cases of illness and death and even widespread epidemics were caused by typhoid, this disease has become rarer. It prevails, however, largely in the country and in many cities. In the 20 years from 1877 to 1896 49,948 persons died from typhoid in the towns of Germany which have population of not less than 15,000, being a yearly average of 2,497 deaths for the whole empire; still, since 1877, there has been a steady decline in the number of deaths from typhoid. In the 5 years from 1877 to 1891 the average was only 2,269 annually, although there has been a great increase in the urban population during the same period; from 1892 to 1896 the average was 1,666, and in the year 1897 there were only 1,552 cases of death from typhoid.—[*Public Health and Marine-Hospital Service.*]

3.—Facts that Contradict the Accepted Odontoblast Theory.—M. Morgenstern objects to the theory that the odontoblasts are perennial and that they at the same time perform the functions of nutrition, sensation, and of metaplastic transformation as regards the dentin. He presents illustrations showing that at least in the earliest developmental stages of the teeth an odontoblast originates from several cell units, that during the different periods of tooth formation a multiple layer of odontoblast cells can be demonstrated, that finally the external rows undergo metaplastic transformation so that they disintegrate. Replacement occurs by proliferation of the small underlying pulp cells that are connected by protoplasmic anastomoses with the dentin cells. The cells within the dentin are not invading leukocytes, but mesodermic and dentin cells that have been passively enclosed. Dentin, under the influence of irritants, may be formed without the typical layer of odontoblasts, which is merely a transitory stage. The pulp becomes included in the process of dentin formation and consequently grows smaller and smaller. He shows the dentin fibers originating from cells deeper than the odontoblasts. He believes he has definitely solved the question of the sensibility of dentin by demonstrating the entrance of axis-cylinders. [H.M.]

4.—Diabetes and Obscure Physiology.—C. Ramus reports the results of a series of experiments, and adduces those of other writers, these in connection with each other showing that in normal blood, dextrose undergoes chemico modification before absorption by the tissues, developing alcohol, which is present in minute quantities in the urine of total abstainers; that in chemically pure solutions of dextrose and levulose treated with pancreatin, sugar is lost and alcohol (and carbonic acid?) developed, the change being more marked in the case of levulose, the agent being an enzyme normally present in blood and having its origin in the pancreas alone, for when that organ is removed dextrose remains unchanged. The disturbance of this function initiates diabetes mellitus. The demonstration of this enzyme was the object of the experiments. The principal source of error is infection with saprophytic bacteria. The absence of glycogen from the liver in diabetes is due to overstimulation of its nervous mechanism by the demand of the tissues for alcohol not now elaborated by the pancreatic enzyme. Levulose and probably lactose is more easily converted into alcohol than dextrose, hence milk is comparatively well tolerated. The digestive functions of liver and pancreas are diminished by the other demands made on their activity, thus favoring the development of acid substances ultimately changing the reaction of the blood. If the writer's theory is correct, the importance of alcohol in treatment is correct. Pancreatic extracts could be useful only in large quantities with or preceding meals. He thinks mescal de tequila, a fermented liquor from the maguey plant may have specific influence on the kidneys. In health man needs no ready prepared alcohol, except such as occurs naturally in some of the foods. [H.M.]

5.—Radium and Radiant Energy.—J. Inglis describes this new element with a history of its discovery, the latter bringing about almost a revolution in our theory of matter. It practically establishes the Thomsonian corpuscle theory, one atom of radium containing 120,000. The unknown radiations traversing space are arrested and transformed into radioactive energy by radioactive substances. The corpuscles that flow between the atoms are negative, and may be drawn out of the straight path by magnetism. Whenever there are 34,000 of these

electromagnetic undulations we see light; if 61,000, violet light. The discovery of such elements as radium we owe to spectrum analysis. It is found in pitchblend, and belongs to the alkaline group with calcium, strontium, barium. It is more valuable than diamonds, and is used to distinguish the real from the spurious. It maintains a temperature of 2° to 5° above the surrounding atmosphere. One grain will melt a grain of ice every hour. Long months of activity show no chemico, microscopic, or spectroscopic change. Its weight remains the same. Its ray penetrates opaque substances like the röntgen ray. A piece carried in a glass tube in the pocket will set up a dermatitis. The source of its energy is unknown. It may in time evolve into another simple body or may be capable of utilizing some unknown radiations which cross the space. Radium induces an activity which persists, while the activity of the röntgen ray ceases on the removal of the rays. It has placed the first question mark against the principle of the conservation of energy according to Kelvin. It has marked bactericidal properties. Normal salt solution may be impregnated and used as a spray. It inhibits growth of diseased tissue, and has been successfully used in cancer, lupus, and is suggested for optic atrophy. It requires no apparatus but a test-tube, and is free from wear and tear, and is portable. [H.M.]

6.—General and Professional Education.—A. T. Hadley believes in encouraging men to do the preliminary work for their several callings while they are in the broader atmosphere of the college rather than in the narrower atmosphere of the professional schools. The professional course secures intensity, but there is danger of fostering the spirit of commercialism, and undue exaltation of those elements of study and practice which form the basis for triumphs of technical skill, and a sort of tradesunionism which affects adversely the political and moral influence of the physician. [H.M.]

Boston Medical and Surgical Journal.

February 4, 1904. [Vol. CL, No. 5.]

1. Report of Cases of Trephining for Epilepsy. JOHN C. MUNRO.
2. Some Conclusions Based on a Study of 134 Cases of Calculus in the Ureter: with a Report of Three New Cases. BENJAMIN TENNEY.
3. Decapsulation of the Kidney. EDWARD REYNOLDS.

1.—Trephining for Epilepsy.—John C. Munro reports 11 cases of trephining for epilepsy. He states that in practically every one of these cases there was some pathologic lesion or abnormality found at operation but vaguely suspected beforehand, and, although the results so far obtained in these cases are at the present time somewhat discouraging, the author reports the cases in the hope that such report may add something to our knowledge in these cases and enable us to arrive at some conclusion in regard to the relatively few cases which are amenable to surgical treatment. He holds that, of course, in the large majority of instances surgery is not indicated in epilepsy but there does remain a certain percentage of cases, even without the previous history of traumatism, in which it is proved that surgery will give relief. A detailed report of the 11 cases is given but is too detailed for valuable abstract. [A.B.C.]

2.—Conclusions Based on a Study of 134 Cases of Calculus of the Ureter.—Benjamin Tenney reports 3 new cases, and a study of 131 additional cases. Of these 134, 12 were relieved by proceedings other than surgical; of the 122 patients operated upon, 98 recovered and 23 died. Eleven of these deaths occurred in the 21 cases operated upon while suffering from anuria or partial anuria, making a mortality of 52% in these cases. Of the 15 cases suffering from pyelonephritis there was a mortality of 47%, excluding the anuria and pyelitis cases. There remain 85 patients operated upon without such complication, and among these there were 5 deaths. His conclusions are as follows: Intermittent pain on one side, with varying amounts of red blood in the urine, are constant symptoms of stone in the ureter. Though the best means of locating stones, the röntgen ray cannot yet give evidence sufficient in itself to warrant us in operating or refusing to operate on certain cases. If a calculus starts from kidney to bladder, it is likely to catch within an inch or one of 3 places, all of which are accessible to the surgeon through extraperitoneal openings. A single calculus is the rule, but the exception occurs, according to these

cases, about once in 8 times. The opening in the ureter or kidney pelvis for removal of the calculus should be sutured if possible. Both sorts of suture materials have been used with equally good results, and wounds in both locations apparently heal equally well. The recovery is only delayed if sutures are not used. A calculus in the ureter is a menace not only to health but to life, and its removal is an operation of low mortality, provided it is undertaken before secondary changes appear in the kidneys. [A.B.C.]

3.—Decapsulation of the Kidney.—Edward Reynolds reports 4 cases in which he operated for nephritis, slashing the capsule in several places parallel to the long axis of the organ, rather than doing a complete decortication. He believes that the relief obtained in either case is a result of reduced tension upon the organ. In two of his cases in which the disease was apparently unilateral, relief from symptoms occurred. In the other two the disease was bilateral. One was distinctly improved, while the other showed no permanent improvement. His conclusions are: 1. We must admit that our present knowledge of the pathologic physiology of renal disease is still defective, but we are justified in believing that nephritis has, as a rule, an infective origin, and probably that the defective renal drainage, due to swelling of the organ within a rigid capsule, plays a part in maintaining the disease. 2. The cases in which general uremic symptoms are more prominent than the physical signs obtained on the examination of the urine are unpromising cases for operation. 3. Where the urinary signs and constitutional depression outweigh the distinctly uremic general symptoms, we may regard the cases as favorable for operation. 4. Where one kidney is mainly or predominately affected, a unilateral operation upon that kidney offers an excellent chance of prolonged improvement in health, if not, indeed, of ultimate cure. 5. In women, in whom ureteral catheterization involves little trauma and less risk, all cases of chronic nephritis should be subjected to ureteral catheterization and the unilateral ones selected for operation. [A.B.C.]

Medical Record.

February 6, 1904. [Vol. 65, No. 6.]

1. Some Groups of Kidney Disease. FRANCIS DELAFIELD.
2. Some Modern Views of Gastrointestinal Troubles and their Treatment by Massage. GUSTAF NORSTRÖM.
3. Practical Points on Hernia. F. D. GRAY.
4. Orbital Cellulitis: Empyema of the Ethmoid Cells and the Frontal Sinus: Abscess of the Frontal Lobe: Pneumococemia: Death. E. GRUENING.
5. Unusual Sequels of a Submammary Hypodermoclysis. O. PAUL HUMPHSTONE.

1.—Some Groups of Kidney Disease.—F. Delafield discusses the kidney lesions occurring in the course of infectious diseases, differentiating those accompanying influenza, scarlatina, diphtheria, yellow fever, and acute yellow atrophy. An important group is those associated with endocarditis. He describes 7 varieties, also the various types accompanying pregnancy, those with anemia in children and young adults, and other forms, acute, recurrent, and continuous. The groups are classified clinically rather than pathologically. [H.M.]

2.—The Treatment of Gastrointestinal Troubles by Massage.—Gustaf Norström discusses the clinical results of massage of the stomach, based upon a long experience, and he shows the relation which exists between the general improvement that is said to follow and the chemic activity of the stomach. He reports a number of cases, such as chronic gastritis, hypochlorhydria, atony of the stomach, dilation of the stomach, hydrochloridia, diarrhea, cramps at the pylorus, constipation, intestinal paresis, intestinal atony, etc., cured or much relieved by massage. He says: Massage influences the glandular elements of the stomach, modifying the chemic action. It tends to approach the relations expressed in the formula to the normal relations. It reestablishes the equilibrium in the components of the gastric juice, lowering them when excessive; raising them when deficient. It acts particularly upon the "evolutif" troubles, in increasing and regulating in a constant and manifest manner the evolution of digestion. [A.B.C.]

3.—Practical Points on Hernia.—F. D. Gray says:

Never forget the possibility of an unsuspected incipient or small hernia, as a possible cause of obscure abdominal symptoms or of obstruction; remember the usual as well as the ordinary locations of hernia; never practise taxis or delay operation in strangulated cases, nor neglect to open the sac and carefully inspect the contents; bear in mind the simple problem of radical cure, restoration of smooth flat peritoneum at the ring, and narrowing or closure of rings and canal, with peritoneum, aponeurosis, and muscle as building materials; transplantation of the cord is not an essential of the Bassini or of the Halstead method; a successful operation on inguinal or femoral hernia dispenses with the necessity for even a temporary truss, but after cure of umbilical or ventral hernias a well-fitting abdominal supporter is a comfort; removal of the entire sac is not always necessary, and in the inguinal variety the distal portion is better left than to risk injury of the cord by a difficult and tedious dissection. It should be remembered that in childhood all forms of hernia are usually curable by persistence in the use of a suitable truss, while after 55 the mortality rate increases, and as activity usually then decreases, a truss answers very well. Young and middle-aged adults—especially males pursuing an active life—ought by all means to have the benefit of an operation. [A.B.C.]

4.—Orbital Cellulitis with Abscess of the Brain.—E. Gruening reports that a man of 26 suffered from chronic supuration of the ethmoid cells and frontal sinus; the infection was pneumococcus in variety as shown from the bacteriologic examination of the discharged pus. Infection occurred by way of the nose, thence to the ethmoid cavities, the orbit and the brain. He was admitted to the hospital with his left eye chemotic, both lids swollen and the globe forced downward and forward. Operation evacuated a quantity of pus from the orbit. Three days later, the patient not having progressed satisfactorily, the original incision along the inner margin of the orbit was extended, the inner plate of the orbital process removed, pus found, and a sinus leading through the dura was followed which ended in an abscess cavity in the frontal lobe of the brain. The abscess was evacuated, flushed, and drainage instituted, but the patient died 5 days after the second operation. Microscopic examination of pus from the brain abscess showed pneumococci in great numbers. [A.B.C.]

5.—Unusual Sequels of Submammary Hypodermoclysis.—O. P. Humpstone reports that a woman patient during delivery suffered such hemorrhage that hypodermoclysis was performed; 600 cc. of salt solution was injected, half under the left breast and half under the right. The injection was done rapidly, owing to the serious condition of the patient, massage being employed meanwhile. The fluid was promptly absorbed from beneath the left breast, but not from the right, which remained distended. On the fourth day an attempt was made to aspirate the fluid, without success, and an incision an inch long was made and 200 cc. of turbid fluid and sloughing material evacuated. Cultures were negative, no milk had appeared in either breast. On the second day after incising the breast 225 cc. of milk escaped from the sinus but none could be expressed from the nipple; the other breast did not functionate. Belladonna ointment and a tight bandage caused a cessation of milk secretion in the right breast within 4 weeks and the breast healed spontaneously. Humpstone says: Hypodermoclysis should, under all conditions, be given slowly and not too hot. Particularly when, because of shock, the lymph sinuses are slow in absorbing the fluid. If a "water boil" is formed it should be evacuated promptly to prevent sloughing of the under surface of the breast, thus opening milk ducts which in a pregnant woman may secrete and delay prompt healing. [A.B.C.]

New York Medical Journal.

January 30, 1904. [Vol. LXXIX, No. 5.]

1. A Case of Purulent Pericarditis, Secondary to Pneumonia, with Operation and Recovery. J. A. SCOTT.
2. Solitary, or Fused, Kidney, with Report of a Case. WARREN A. DENNIS.
3. Some Investigations of a Bacterial Treatment of Tuberculosis. STEPHEN J. MAHER.
4. Public Health and Food Preservatives. R. G. ECCLES.

1.—Purulent Pericarditis.—J. A. Scott reports a case of purulent pericarditis, secondary to a double pneumonia, in which an operation was followed by recovery. On the thirteenth day the pericardium became involved. An exploratory needle was inserted in the fourth right space, and about 10 cc. of turbid, light-greenish fluid secured, in which pneumococci were found. Later, the pericardium was aspirated, and 14 oz. of fluid removed, with almost immediate relief to the urgent symptoms. Seven days later, reaccumulation had occurred, and under cocaine anesthesia the fifth space was incised in site of normal apex beat, the pericardium opened, and between a pint and quart of nonodorous pus slowly liberated. The drainage-tube was removed 26 days later. The features of interest in the case are: 1. The absence of a leukocytosis during the pneumonia, and its development with the pericarditis. 2. The absence of the pericardial friction, both before and after the pericardium was opened. 3. The absence of fever—subnormal temperature—with pus in the pericardium. 4. The recovery of the patient without the physical signs of an adhesive pericarditis. [C.A.O.]

2.—Fused Kidney.—W. A. Dennis reviews this condition and reports the case of a woman of 26, who was operated on for movable kidney. On account of the size of the kidney (between 6 inches and 7 inches long) a nephrotomy was done, and nothing discovered abnormal. The disagreeable symptoms were relieved; with the closure of the wound, however, there was a gradual return of all the symptoms. The kidney remained firmly fixed, but fluctuated in size from time to time. Cystoscopic examination with catheterization of the ureter failed to disclose any obstruction, and the urine flowed freely from the catheter. It was seen to escape normally from the left ureteral orifice. A nephrectomy was done, and over the lower half of the kidney, which at the time of the previous operation had been supported by gauze, the adhesions were so dense that the capsule was stripped back in freeing the kidney and tied together with what appeared to be a broad adhesion. The patient passed no urine after the operation and died uremic at the end of 7 days. An examination of the specimen showed that the adhesions about the lower half had concealed a second pelvis and ureter and the lower portion represented the displaced and fused left kidney. An autopsy showed that there was no kidney in the left loin and that the lower ureter crossed the median line to the left side just below the promontory of the sacrum, behind the rectum, and in front of the great vessels, and that it then followed along the left wall of the pelvis and opened into the bladder at the normal site. [C.A.O.]

3.—Bacterial Treatment of Tuberculosis.—The germ used by S. J. Maher in his investigations is an organism of nearly the same size and shape as the tubercle bacillus, and is called by him the x bacillus. It is found in the whey of the milk from tuberculous cows. H. W. Conn says it does not exactly agree with any described species, except *B. mycoides* III, Conn, and it differs slightly from this. In concluding his report, he emphasizes the following points: 1. X bacillus can, with absolute safety, be injected alive and in pure culture into the human system. 2. After injection it remains alive in the human system often for weeks. 3. After injection it causes a variable febrile reaction which is never serious. 4. After injection it has been found in the urine, and blood, and sputa of persons injected. 5. After injection into the groins of persons suffering from tuberculosis there is often a subjective sense of local reaction at the site of the tuberculous lesion. 6. After injection into the connective tissue about tuberculous fistulas in ano, a marked improvement, even to the closing of the fistula, has followed. 7. After injection into the ear of persons suffering from tuberculous otitis media, such persons have been in no wise harmed but have, in several instances been cured of otorrhea and other symptoms. 8. After its application on gauze or cotton packing to sinuses leading from carious bone, supposedly tuberculous, such sinuses and caries have healed with surprising promptness. 9. Its hypodermic injection into patients suffering from tuberculosis of the lungs has been followed in many cases by marked relief. 10. Its instillation into the open tuberculous pleural cavity has caused the drying up of a purulent discharge. 11. Its hypodermic injection into tuberculous patients has, in several demonstrable

cases, been followed by the apparent cure. 12. As a valuable scavenger of the tuberculous human system, the x bacillus claims the interest of the medical profession for the further reason that it grows in acid or alkaline media, that its product is alkaline, that it grows in the presence or absence of air, that it feeds only on dead matter, that it grows more quickly and has more vitality than the ordinary pus-producing germs. [C.A.O.]

4.—Food Preservatives.—R. G. Eccles enters a plea in favor of the judicious use of food preservatives. He calls attention to the fact that during the 20 years that modern preservatives have been growing in favor and the quantities used of them increasing, public health has been steadily and surely improving, and the deathrate diminishing. He says that, no doubt, general sanitation deserves the chief credit for the lessened deathrate, but if chemie preservatives were half as injurious to public health as the opponents of them would like to have us believe, the great bulk of sanitary effort should have been neutralized. [C.A.O.]

Medical News.

February 6, 1904. [Vol. 84, No. 6.]

1. Some of the Physical Properties and Medical Uses of Radium Salts: With Report of Forty-two Cases Treated by Pure Radium Bromid. FRANCIS H. WILLIAMS.
2. Late Results of Röntgen Ray Treatment of Sarcoma. WILLIAM B. COLEY.
3. Abdominal versus Vaginal Hysterectomy. JOHN B. DEEVER.
4. The Occurrence of Tenia Nana in Texas (the First, or at Least, the Second, Reported Case in North America). JOHN T. MOORE.
5. Two Advantageous Procedures in Anesthesia Work: Report of Cases. VICTOR C. PEDERSEN.
6. Laboratory Aids to Diagnosis for the General Practitioner. VICTOR A. ROBERTSON.

1.—Forty-two Cases Treated by Radium Bromid.—Francis H. Williams states that of the 42 patients treated, 9 were suffering from acne, 2 each of eczema and psoriasis, and 4 of lupus vulgaris. Of the 33 remaining, 1 was a keloid, 5 were cases of rodent ulcer, 23 of epidermoid carcinoma, and 4 were cancer of breast. The keloid case has improved, 2 of the 5 cases of rodent ulcer have healed, and 3 show improvement. Of the cases of epidermoid cancer, 11 have healed and 12 are improving, and of the 4 breast cases 3 are improving. The author made experiments to test which were the more beneficial, the beta or the gamma rays from radium; these showed that the beta rays do not penetrate and are therefore suited for superficial treatment, while the gamma rays have a marked power of penetration. His conclusions are as follows: Experience thus far teaches that there is much similarity between the action of the radiations from radium and the röntgen rays; that if the results obtained by radium prove permanent, this new therapeutic agent will be largely used instead of the röntgen rays, but that the two will supplement each other. 1. Certain diseases promise to yield more readily to treatment by radium and others to the röntgen rays. 2. A disease that has attacked different parts of the body of a given patient may be better treated in certain regions by radium and in others by the röntgen rays. 3. It is quite possible that in some cases the 2 remedies used together on the same area and at the same sitting may accomplish better results than either alone. [A.B.C.]

2.—Late Results of Röntgen Treatment of Sarcoma.—William B. Coley has observed 103 cases of malignant tumor treated with röntgen rays; 30 were recurrent carcinomas of the breast, 42 sarcomas in various localities, 28 cancers of the head, face, and neck; and 3 miscellaneous. He reports a number of cases, and concludes as follows: We are already beginning to see the evil effects of the too optimistic reports as to the value of the röntgen ray in cancer. Pusey and Caldwell, in their carefully reported series of cases, state that of 27 cases of superficial epithelioma, 21, or 77.7% are, as far as can be told from present conditions, cured. Yet only 7 were well over 8 months; and only 1 as long as 15 months. The use of röntgen ray in cancer should be limited to recurrent and inoperable cases, with the sole exception of small superficial epithelioma of the face. Even here the results of excision will prove better and more lasting, save in the proximity of the eyelids and nostrils. It is most misleading to report as cures, cases in which malignant tumors have merely disappeared under the influence of the röntgen ray, since speedy return is

the rule rather than the exception. At the present moment there is no evidence to prove that any permanent cures have been obtained, save possibly in the case of rodent ulcer. [A.B.C.]

3.—Abdominal Versus Vaginal Hysterectomy.—J. B. Deaver discusses the methods of hysterectomy, with special reference to operation as a remedy for cancer of the uterus. If the uterus is adherent and fixed in the pelvis, the broad ligaments extensively infiltrated, and the vaginal vault involved, operation is inadvisable. When operation is advisable he opposes vaginal hysterectomy for cancer of the cervix except in the presence of obstacles necessitating such a course. Vaginal operation suffers from the imputation of being an incomplete operation, dangerous to the ureters and liable at any time to give rise to severe secondary bleeding. The writer does not think any necessity exists to dissect out the iliac glands, as the additional mortality from operation is not repaid by lessened recurrence. In performing abdominal hysterectomy for carcinoma, he first cures the cancer area and cauterizes with pure carbolic acid, and then recleanses the vagina thoroughly. He does not make a median incision, but prefers to incise through either rectus muscle close to the median line, thus avoiding hernia. Deaver does not use the cautery of Downs, but is satisfied with his results by the use of suture and ligature, and thinks those cases calling for the cautery to destroy tissue are not adapted to radical operation. He adds that a multiplicity of instruments, awkward to handle, and which tend to make a complicated out of a simple operation, is to be deprecated. [W.K.]

4.—Taenia Nana in Texas.—J. T. Moore reports a case in which the parasite was contracted near Galveston. He describes the characteristics of both genus and species, illustrating from his own specimen. The ova are perhaps ingested with water or vegetables. From irritation there is apt to be loss of appetite, diarrhea alternating with constipation, colicky pains, and nausea. The nervous symptoms are headache, disturbance of vision, dizziness, melancholia, and in many cases attacks of epilepsy. Anemia follows later. Male fern is the best drug. In 1873 another case was reported and the specimens placed in the College of Physicians of Philadelphia, but Leuckhart is disposed to think the specimen was *Tenia flavopunctata*. This would make the author's the first recorded case of *T. nana* in North America. [H.M.]

5.—Advantageous Procedures in Anesthesia.—Victor C. Pedersen advocates anesthesia by means of a nitrous oxid ether sequence. The first procedure is an advantageous means of administration of the nitrous oxid ether sequence. Strictly speaking, it is a new sequence in which the series is nitrous oxid, then nitrous oxid and ether combined, and finally ether alone. The purposes of the technic are to avoid producing any gas cyanosis, to induce ether narcosis very slowly without exciting any reflexes, such as coughing, and finally to obtain a full degree of ether narcosis with the utmost safety and convenience to the patient. Explanation is given as to how this is accomplished and the results of his experience given. Pedersen has tried this method in 150 patients, only one of which showed the usual gas cyanosis in more than a moderate degree. The author also explains how an anesthetic should be given in operations upon the kidney; the point being that the patient is first anesthetized in the ordinary position, and when ready for operation is placed prone. To permit the head and neck to be free, both for manipulation by the anesthetizer and for respiratory comfort, a sandbag is placed underneath the upper part of the chest, the point of each shoulder resting thereon. This brings the pressure of the chest upon the shoulders and upper sternum instead of the base of the neck, permitting the patient to breathe with comfort, and enabling the anesthetizer to manipulate the head with ease. [A.B.C.]

CLINICAL MEDICINE

DAVID RIESMAN

A. O. J. KELLY

EDITORIAL COMMENT

The Symptomatology of Pancreatic Lithiasis.—The symptomatology of pancreatic calculi is one of the most interesting chapters of this affection, both on

account of its great variableness and diagnostic importance. The symptoms are objective and functional. The former are rare, usually in the form of a cyst produced by obstruction of the canal of Wirsung or the presence of one or several calculi in the feces. They are with difficulty found in the stools as they are present in the form of white sand or calculi composed of carbonate of lime. Regarding the functional symptoms, let it first be said that the pancreas has two functions—an internal and an external secretion—both of which are changed by the presence of calculi. The principal symptom of the first, which may be considered as somewhat pathognomonic is pancreatic colic, similar in many respects to biliary or nephritic colic. Those due to pancreatic calculi are most difficult of recognition, but at all events less intense probably on account of the weak contractility of the canal of Wirsung; they are quite acute, and the attacks come near together. The site of the pain is also characteristic, situated between the umbilicus and epigastrium; it may also extend along the costal border on the left, reaching the spine and left shoulder, or to the lumbar region on the same side. It is difficult to differentiate it from painful affections of the stomach or neighboring viscera. The patient complains of a feeling of weight in the epigastrium or of repeated attacks of paroxysmal pains similar to neuralgia of the cardiac plexus. The pain is increased by movement, the patient holding himself as rigid as possible, and finally complains of general malaise with cold perspiration and nausea, ending in bilious or alimentary vomiting. These attacks, like biliary colic, may occur before or after meals, or without any regular time. Stearrhea is a common symptom of various diseases of the pancreas, so frequent, indeed, that Moyses, Ancelet, and other authorities have considered it as the principal diagnostic sign of pancreatic lesions. The importance of this condition of the feces is much exaggerated, however, because it is absent in many instances, and it is also present when the pancreas is normal. The characters of fatty stools vary, and in reality have been inadequately studied. The feces in stearrhea is composed of small whitish balls, the size of an olive, and feel unctuous to the touch. These small fatty masses are often mixed with soft or hard matter, but still more frequently the feces are enveloped at the time of defecation by a layer of liquid fat, which soon becomes solid upon standing. The desire to go to stool is increased in frequency because stearrhea acts like a glycerin enema, irritating the sensibility of the rectum. The reality of fatty feces can, however, only be positively admitted after a chemic and microscopic examination has been made. It is well to mix the feces in ether, and after filtration of the liquid a piece of blotting paper will become transparent when dipped in the solution as if oil-soaked. By evaporation the ether leaves a deposit of fluid fat, which burns with a blue flame. Microscopic examination shows fat globules, soluble in ether, and crystalline needles, which after evaporation leave a deposit of fat. Once the diagnosis of stearrhea is made, one should not give it too much importance, for it may be made to disappear by regulation of the diet, or it may be due to suppression of fat absorption by the intestine, when, for example, the thoracic duct is compressed. Stearrhea is an important symptom, inasmuch as it will lead one to suspect a lesion of the pancreas. Lipuria also coexists with stearrhea, but only a few cases are recorded of lipemia. All these symptoms, taken separately, are of no particular value, and no one of them is pathognomonic; their coexistence is a precious diagnostic guide, and cannot lead one into error. Beside these important signs, there is another which accompanies them and confirms the diagnosis, we refer to the syndrome of diabetes with wasting. This, as we know, is produced by the suppression of the internal secretion of the pancreas, and in cases of pancreatic calculi takes on a special physiognomy which should be

studied. At the commencement of the disease, when colics make their appearance, it is only temporary, while the symptoms noted are polydipsia, polyuria, glycosuria and polyphagia, all of which are probably due to an inhibition of both the internal and external secretions of the pancreas, similar to those observed when a renal calculus obstructs one of the ureters. After a few weeks the patient again feels well, but the attacks soon reappear, and with one or two years the calculi produce a profound change in the pancreas in the form of atrophy, thus constituting diabetes with wasting with all its particular symptoms. The debut is so sudden that the patient can tell almost to a day the time that the symptoms commenced. Within a variable time following an attack of pancreatic colic the patient is taken with an intense polydipsia, due, without doubt, to an increase of sugar in the urine. The amount may reach to from 400 gm. to 800 gm. in 24 hours. The quantity of urine is also increased on account of the polydipsia; it is usually clear and limpid, having a density of from 1,030 to 1,040. The urea reaches from 30 gm. to 60 gm. in 24 hours. Whether or not this increase is due to the polyphagia, or not, is as yet an unsettled question. Polyphagia is excessive in these cases, but it would appear that the food ingested does not nourish. These subjects always commence to emaciate as soon as they begin to eat excessively, the loss of flesh being, so to speak, in direct relation to the amount of food taken. The fat rapidly disappears, the muscles atrophy, and memory becomes weak. Physical and genital vigor decline, the patient making his *exitus letalis* in coma or from some inflammatory complication. These various symptoms are due to a functional insufficiency of the pancreas; diabetes with emaciation is not a morbid entity, but is simply a revealing syndrome of this insufficiency. Pancreatic lithiasis consequently has more or less important clinical signs when taken separately, but whose ensemble and coexistence are necessary for a diagnosis. Other less common symptoms may arise, such as intestinal hemorrhage or temporary icterus, but they are exceptional, and in most instances the affection has a nearly identical symptomatology.

REVIEW OF LITERATURE

Radioscopy of Peristaltic Movements.—F. Lommel¹ studied the peristaltic movements of the stomach and intestines of normal, trained dogs, whom he had fed with chopped meat mixed with bismuth, by means of the röntgen rays. The dogs were tied in such a way as to enable the study of the different parts of the gastrointestinal tract with ease. The fact that the dogs were absolutely well adds considerably to the value of these tests. From 2 to 6 minutes after the feeding, the first rhythmic movements could be seen starting from the greater curvature. Within 5 minutes the entire stomach took part in the peristalsis. Ten complete waves occupied usually 120 seconds in all animals, although some slight variations were occasionally seen. Application of heat to the epigastrium did not affect the number or rapidity of the waves. Peristalsis started earlier when heat was applied, and the pylorus opened a little sooner in some of the animals. Application of cold had no influence over the peristaltic waves. If somatose was added to the food, 10 peristaltic movements passed off in 110 seconds and evacuation from the stomach began considerably sooner; if meat extracts were employed, there were 10 waves every 100 seconds, thus proving their value as digestive stimulants; the importance of this, or whether it is important at all, the author is unable to tell. Psychic influences are more important in regard to digestion than physical or chemic factors. Animals not accustomed to laboratories showed no peristaltic waves for hours, while trained animals' stomachs began to digest within a few minutes; even these animals showed no digestion if made uncomfortable in any way, while animals of the first class showed waves as soon as permitted to roam about. This justifies the supposition that the stomach of man is more influenced by psychic

emotions than by therapeutic measures. Examination of the intestines demonstrated antiperistaltic waves and a periodic relation between gastric evacuation and intestinal peristalsis. [E.L.]

The Clinical Relation of Stomach Disorders to Diabetes.—J. P. Sawyer¹ says that comparatively little has been written regarding the relation of these conditions. He gives the histories of 6 diabetics who have shown such remarkable response to measures directed to the local condition of the stomach that he has become convinced of a hitherto overlooked importance of the conditions of the stomach in the treatment of cases of diabetes. The results seem sufficiently uniform to exclude the idea of simple coincidence. The treatment instituted was regulation of the diet but not deprivation, as often employed, and more or less vigorous lavage with alkaline solutions. Two of the cases were particularly interesting as they showed a uniform sugar excretion under lavage once daily while the sugar was at once lowered by a more alkaline solution used twice daily. A striking effect was produced upon the thirst, this being so regular that Sawyer is led to urge the trial of lavage of the stomach with alkaline solutions in all cases where great thirst is noted. The excessive hunger of some of the patients was also markedly lessened. The conclusion of the writer is that the stomach disturbances of diabetes should not be considered as of trifling importance and only due to the sugar in the blood; in many cases they are likely to afford a point of attack by which a degree of relief from distressing symptoms and prolongation of life may be secured better than by other means. [A.G.E.]

Symptomatology of Basedow's Disease.—Bruns² gives a critical survey of the rarer symptoms of 24 cases of Basedow's disease which came under his observation; 20 of the patients were women, 4 were men. Of the cardinal symptoms, tachycardia, exophthalmus, and goiter, he has little to say; the first is very rarely absent, and then only in the first stages of the disease. Graefe's sign was present in 10 cases; it seems to be proportionate to the exophthalmus. Moebius' sign (lack of convergence of the two eyes) was noted often, but Stellwag's sign (diminished number of closures of lid) was rare; in several cases he observed an increase in the amount of winking. Ophthalmoplegia was seen but in one case. Chronic diarrhea is a very frequent and often a very early sign; 11 of his patients suffered from it. Vomiting over a prolonged period was seen 3 times. If the two coexist, the prognosis is grave, on account of the extreme emaciation, which will result. Emaciation may be noted without this, however, and without any apparent cause, and is often interrupted by an equally ununderstandable increase in weight. Polydipsia, polyuria, and bulbinia have been noted. None of his patients had glycosuria. Of cutaneous symptoms, free perspiration is the most frequent; melanosis was seen 3 times. Symptoms of bulbar palsy, mental excitability, and melancholia were observed. One patient presented typical symptoms of Korskov's psychosis. Hysterical attacks were also common. Bruns recommends absolute rest and overnourishment as treatment. He has never had a patient operated on, but believes it to be philosophic treatment, as he shares Moebius' opinion regarding the cause of the disease (intoxication through abnormal thyroid products.) [E.L.]

Dependence of Cyclic Albuminuria on the State of the Circulation.—P. Edel³ made the statement in previous papers that albumin excretion in cyclic albuminuria depends upon difference of blood-pressure, and in this article he presents further arguments to prove that it is due to an insufficient blood supply going to the kidney. He noticed that during the period of fatigue, such patients had a small pulse and invariably the urine contained albumin; during the time when the pulse was strong and full there was no albuminuria; the Riva-Rocci apparatus verified this. Numerous tests with this instrument confirmed this constantly. Such patients were given warm baths, cold washes, were made to climb stairs, and take bicycle trips, always with the same result. During the period of exertion, the pulse showed considerable pressure, the urine

¹ Cleveland Medical Journal, January, 1904.

² Allgemeine Zeitschrift für Psychiatrie, 1903, lx, 751.

³ Deutsche medizinische Wochenschrift, 1903, xxix, Nos. 36 and 37.

¹ Münchener medizinische Wochenschrift, 1903, l, No. 38.

contained no albumin; during the period of rest, the pulse sinking in volume, albuminuria began. The blood-pressure always sank abnormally low in these patients after exertion. Artificially produced disturbances in respiration produced the same fatigue and urinary result, although the urine was perfectly normal before. The underlying cause of the condition is most likely a weakened cardiac organ and bloodvessels, which are too weak to contract when increased cardiac activity demands it. He concludes from this that cyclic albuminuria should be treated by measures to tone up the heart muscle, instead of rest, as usually advocated. He has cured cases of cyclic albuminuria by treating along these lines (gymnastics, etc.), and has always seen good results in treating chronic nephritis the same way. While the blood-pressure is high, the kidneys are capable of taking care of all the fluids without showing any disturbance, but as soon as their nourishment diminishes in amount, albumin shows itself. Diuretics benefit by increasing the circulation. [E.L.]

Second Attack of Scarlet Fever within Eight Months.—W. A. Dunckel¹ reports this case which occurred in a boy of 3. The first attack was typical as was also the second with the exception* that the desquamation was somewhat irregular. That phenomenon appeared on the seventh day and was complete in 3 days. The eruption was more pronounced than during the first attack. About the fourth day of the second attack both the mother and nurse had redness and swelling of the fauces and tonsils, chilly sensations, headache, pain in the lumbar region, moderate prostration and febrile disturbance. Neither developed a rash. Dunckel thinks it less difficult to believe that the immunity conferred by an attack of scarlet fever is short enough to allow a second invasion of the same disease within 8 months than to believe the alternative—that there can be 2 diseases so nearly alike, varying only as to the eruption and the severity of desquamation. [A.G.E.]

GENERAL SURGERY

MARTIN B. TINKER

A. B. CRAIG

C. A. ORR

REVIEW OF LITERATURE

Operative Treatment of Hernia in Infants and Young Children.—Robert Campbell² states that the essential cause of hernia in children is the presence of a patent funicular process, and therefore any method of treatment which aims at curing the deformity must secure obliteration of this pouch. He is opposed to the use of a truss; in these cases it is tedious, difficult, uncertain, and the patient constantly runs the risk of strangulation. All hernias in children should be treated by operation, with the possible exception of easily controlled hernias in children of well-to-do parents. He says: (1) By operation the funicular process is completely removed; (2) the time in curing a hernia by operation is about a fortnight, as compared with 3 years by the use of a truss; (3) the cure by operation is almost certain to be permanent; (4) the risk of operation is at most not greater than the risk of death from strangulation during the use of the truss. Campbell reports 114 cases of radical cure in children. All the cases were inguinal; over two-thirds of them were leftsided; 109 were males and only 5 were females. The age at the time of operation varied from 3 weeks to 10 years; in about 9 out of every 10, though there was a funicular process, it did not communicate with the vaginalis testis; there were 8 cases of strangulation. The mortality was nil. A modified Mitchell-Banks operation was used in children under 2 years of age, unless the hernia was large; in older children and large hernias the method of Bassini was selected. [A.B.C.]

Torsion of the Pedicle of the Spleen.—A woman of 37, who had given birth to 5 children, was again seized with violent vomiting, and dated a sixth impregnation from this, as she had been wont to vomit with each of the previous ones. One night she went to bed apparently very well, but awoke at midnight with vomiting, violent pain, and tenderness in the left side; a large mass could be felt beneath the border of the

left ribs, which was diagnosed either as a strangulated floating kidney or twisted splenic pedicle. An operation proved the latter to be the correct diagnosis, the spleen being turned on its long axis. It was not displaced to any great extent, and differed from other reported cases in these 2 points. The spleen was removed and the patient recovered. In spite of the marked torsion, the circulatory disturbance was but slight. K. Buedinger,¹ who reports this case, is not clear about the etiology, but he is sure that it is not due to an abnormally long splenophrenic ligament; a weakening of its supports, associated with enlargement of the organ, had probably more to do with it than anything else. An operation is indicated when the floating spleen is the cause of occasional or permanent disablement; he does not advise operation simply because a torsion may be thought to be possible, as splenectomy is often followed by very serious consequences. [E.L.]

Traumatic Aneurysm of the Gluteal Artery.—Allan H. Muir² reports the case. A man of 28 was admitted, thought to be suffering from an abscess of the hip following an injury 4 months previously. He had fallen and struck on his right buttock. A swelling the size of a hen's egg almost immediately developed, and the patient was confined to bed for 5 weeks, during which time and later the swelling gradually increased in size, till it now covered almost the whole of the upper gluteal and iliac region. Pulsatile motion could be observed and bruit could be heard. Aneurysm of the right gluteal artery was diagnosed. The patient was given increasing doses of potassium iodid, and put to bed on modified Tuffnel diet. For 3 weeks improvement could be noted, then the tumor began to increase in size, and breaking of the skin seemed imminent. Operation being decided upon, laparotomy was performed and pressure made upon the right internal iliac artery, then a long incision was made in the line of the gluteal artery. The large sac was opened and evacuated, the rupture in the gluteal artery found, that artery ligated in 2 places and the wound closed. The patient made a good recovery. Incidentally an ununited fissure fracture was found extending from the top of the sciatic notch to the crest of the ilium. [A.B.C.]

Hemiplegia Immediately Following Ligature of the Carotid.—M. Beutter³ reports a case in which the submaxillary gland was removed for malignant growth, during which operation it was necessary to cut the right common carotid between 2 ligatures. Twenty minutes later, while the patient was recovering from the anesthetic, his left arm and leg became completely paralyzed. This paralysis almost completely disappeared within 2 or 3 weeks. The explanation is doubtful. It may have been due to anemia of the affected hemisphere, or to a congestion, owing to paralysis of the vasomotor nerves included in the ligature of the carotid. [B.K.]

Gangrene of Meckel's Diverticulum.—E. Oliver Ashe⁴ reports the case. The patient was a boy who with his parents lived in South Africa. The patient, who was suffering from violent abdominal pain, was seen by a physician, who ordered him taken to Kimberley for operation. The distance was 60 miles by wagon and then 40 miles by train. There was great distention of the abdomen, and operation revealed a Meckel's diverticulum, 7.5 cm. (3 in.) long, which sprang from the ileum about 10 cm. (4 in.) from the cecum. The distal half of this diverticulum was gangrenous. The whole was cut off close to the ileum, and closure effected with Lambert sutures. The vitality of the patient had been so exhausted by the long delay, the extensive journey, and the operation that he died 6 hours after the latter was completed. [A.B.C.]

True Acquired Diaphragmatic Hernia.—A woman of 75, who had suffered for years with an umbilical hernia, which often became incarcerated was operated upon with apparently very good results. She collapsed on the thirteenth day after the operation, dying very soon after. F. Lucksch⁵ performed the autopsy, which revealed the case to have been one of acquired diaphragmatic hernia instead of an expected congenital defect in the diaphragm. The muscle fibers between

¹ Wien. klin. Woch., 1903, xvi, 269.

³ Lyon Médical, December 27, 1903.

⁴ British Medical Journal, July 25, 1903.

⁵ Prager medicinische Wochenschrift, 1903, xxviii, 169.

¹ Archives of Pediatrics, January, 1904.

² The Lancet, January 9, 1904.

costal and sternal portions of the diaphragm had been forced apart and the intestines forced their way through. The cause of the hernia is found in the frequent incarcerations, during which the inflated intestines were forced against the diaphragm ultimately forcing its fibers apart. [E.L.]

Intussusception of Vermiform Appendix.—F. P. Conner¹ reports that a boy of 9 suffered from the symptoms of intussusception. Laparotomy revealed an intussusception, which was mostly of ileum. This was easily reduced, when a marked dimple on the posterior and inner aspect of the cecum was observed. Investigation showed a completely invaginated appendix, the mesentery of which was drawn into the dimpled area. Attempts at reduction were futile, so the caput coli and invaginated appendix were removed en masse, and the opening thus made, closed with tier sutures. Shock was pronounced, but recovery was uneventful. Since the child had received a blow a month previously in the region of the appendix, resulting in nausea and vomiting, Conner feels convinced that this was the cause of the intussusception, which he is of opinion was originally appendiceocecal. The irritation from this polypoid invagination led to the intussusception above. [A.B.C.]

Aerophagy: A Hitherto Undescribed Symptom of Esophageotracheal Fistula.—E. Adenot and L. Cadet² report a case in which there had been steadily increasing difficulty in deglutition and phonation for 2 years. At the time of observation there was complete inability to swallow; attempts to do so caused violent paroxysms of coughing. Cancer of the upper part of the esophagus, with tracheoesophageal fistula was diagnosed. Gastrotomy was decided upon, and at operation it was found that the stomach was enormously distended, and that the distention followed the movements of respiration. Usually in esophageal carcinoma the stomach is small and retracted. The above diagnosis was practically confirmed at autopsy. Explanation for the gastric distention was that a negative pressure in the esophagus during inspiration caused a rush of air through the fistula into that organ; during expiration this air was forced into the stomach. [B.K.]

Operative Treatment of Cranial Depressions in Infants. J. Henderson Nicoll³ reports 6 cases, 4 of which were of birth fractures and 2 were fractures due to injury in infancy; operation was similar in principle in all the cases. This consisted in inversion of the depressed area of bone. The scalp and pericranium having been reflected in one layer, the depressed portion of skull was cut by trephine (1½ in. to 2½ in. in diameter) inverted on the dura mater, and fixed in position by suturing over it the replaced skull and pericranium. The result in five instances was complete correction of the deformity and in the sixth partial correction. Failure in the one instance was due to the use of a trephine which was too small, and therefore the entire area of depression was not removed with the button. A striking feature in each instance was the rapidity of bone union observed at the end of a week. When the scalp sutures were removed the inverted disc of bone was in every instance found firmly united to the skull. [A.B.C.]

GYNECOLOGY AND OBSTETRICS

WILMER KRUSEN

FRANK C. HAMMOND

EDITORIAL COMMENT

Uterine Disease and Constipation.—The frequent coincidence of constipation and uterine disease is a fact of diurnal experience in the practice of every medical man. And the peculiar obstinacy of this symptomatic form of constipation is quite as noticeable as its frequency. All the items of the approximately endless roll of laxatives and purgatives, intestinal lavages, abdominal massage, electric stimulation, resort to the special routine treatment carried out at the health resorts established in connection with the noted mineral springs—all are tried in turn, all give temporary relief, and all fail to establish a permanent cure. But the fact is none the less

true, that in many cases of obstinate constipation, in which no definite symptoms have been referred by the patient to the generative organs, the causative influence of the uterus is frequently overlooked. Dr. Marchais has recently published a series of four such cases; a consideration of which cannot fail to be instructive. The first was that of a lady aged 33, who married at 20—in a state of perfect health. She had borne two children without any special trouble, except that in her second confinement, as the uterus appeared somewhat inert, the forceps was employed. No immediate trouble appeared to result. But from that date she became a victim of obstinate constipation and suffered frequent intestinal pains. From time to time false membranes and slight hemorrhagic discharges passed from the bowel. She underwent the various specific treatments, without permanent relief. But the uterus had not been examined. The history induced Dr. Marchais to suspect its influence. He found the organ prolapsed to a moderate extent; and after application of gynecologic kinesiotherapy, combined with massage of the abdominal wall and gastrointestinal massage, a satisfactory cure was soon effected. The second case was nearly similar, but the complete absence of any complaint on the part of the patient regarding the condition of the pelvic organs—or abdominal organs generally, excepting the negative symptom of obstinate constipation—allayed suspicion; and the patient's complaint was referred to atony of the muscular coats of the intestine. The case was accordingly treated by massage, but no improvement resulted. Suspicion was then aroused and a vaginal examination revealed partial prolapse of the uterus, which was also enlarged and the "annexes" of the right side were involved. A course of gynecologic kinesiotherapy was then adopted, and a thoroughly satisfactory result was soon obtained. The conclusion drawn was that although a condition of general atony of the intestine was undoubtedly the primordial cause of the special symptom present, the latter would never have reached the prominence which it displayed without the pressure on the rectum caused by the displaced uterus. The third of Dr. Marchais' cases was that of a woman of 29, who had been married at 21, but had never been pregnant. There was the same obstinate constipation, but a complete absence of all other abdominal, or pelvic, symptoms. The patient complained of some lumbar pain during menstruation, but nothing beside. Accordingly, massage was practised for a week and the result appeared quite satisfactory. But, when discontinued, there was an immediate relapse. A vaginal examination was then made and displayed well-pronounced retroflexion of the uterus. There were no adhesions, and no salpingitis, and the derangement yielded to a proper course of gynecologic treatment. The disappearance of the constipation progressed (*pari passu*) with that of the uterine displacement. The fourth case was that of an unmarried woman of 29, who had suffered a great deal of pain, both before and during menstruation, ever since its first appearance—at the early age of 12. Her brother was a medical man, practising in Paris, and had treated her by the usual routine methods, specially including massage and electricity. There were no other abdominal or pelvic symptoms. She had undergone an operation for an urgently acute attack of appendicitis at the age of 25. As in the last-mentioned case, a course of abdominal massage gave temporarily satisfactory relief, but relapse at once occurred when the treatment was discontinued. Local examination displayed the existence of retroversion of the body of the uterus—with the appendages of the right side. The fundus uteri was tumefied and painful to the touch, and pressed on the rectum. Gynecologic therapy was duly carried out and gave relief, which, however, proved to be but temporary. Massage was then adopted with a like result. As there appeared no hope of permanent improvement from such palliative procedures a more radical one was decided on.

¹ Lancet, August 29, 1903.² Lyon Medical, December 27, 1903.³ British Medical Journal, December 19, 1903.

Hysteropexy was performed with success and the result in its effect on the prominent trouble proved satisfactory and lasting. The inevitable conclusion drawn by the author is, that in all rebellious cases of constipation in the female, lesion of the uterus should be suspected, and efficient treatment adopted—palliative or radical.

REVIEW OF LITERATURE

Vaginal Cystotomy for Stone in the Bladder.—C. R. Robins¹ reports 2 cases and concludes that cystotomy is the operation of choice for stone in the bladder. Lithotripsy is often difficult to accomplish, as it is difficult to retain sufficient fluid in the bladder to work the lithotrite with safety, as the urethra permits its passage during the manipulation of the instrument. Extraction through the urethra is only applicable when the stones are quite small, as dilation beyond a certain point is liable to rupture the sphincter muscle and establish permanent incontinence. Suprapubic cystotomy makes a prolonged and disagreeable convalescence and does not drain at the most dependent point or permit of so satisfactory irrigation of the bladder. Vaginal cystotomy is the ideal operation in most cases. It is easily and quickly executed, and if necessary can be done under cocaine anesthesia. It gives the best drainage, if cystitis is present. The only objection that can be urged is the danger of forming a vesicovaginal fistula. He believes that if we refrain from sewing the mucous membrane of the bladder and vagina together and rely instead on a daily opening of the incision, that we will seldom encounter this complication. [w.k.]

A Case of Unusual Obstruction in Labor.—J. Saks² reports the case of a primipara of 38, in whom normal delivery was prevented by what, on vaginal examination, seemed to be an ovarian tumor filling the vagina. But when the abdomen was opened, Saks was astonished to find that the apparent tumor was the inflated large intestine bent upon the sigmoid flexure, and in the abdominal cavity there was a small amount of bloody fluid. After the twist was loosened, it was not judged practicable so to arrange the distended intestines as to make normal delivery possible. Hence a longitudinal incision was made in the uterus and both fetus and placenta removed and uterus and abdomen closed. The patient, however, died the following day. [w.k.]

The Gynecologic Conditions following Placenta Prævia.—Erich Radtke³ has made a study of 80 patients as to their condition following placenta prævia and states that of these 56 retained the power of conception, and 24, or 30% were sterile. Of the 80 patients 23 aborted in the subsequent pregnancy. Seven of these had a previous history of abortion, but the other 16 had not, and as cause of the abortion they were found to be suffering from various pathologic conditions such as endometritis, laceration of cervix, etc. Also 57 of the 80 suffered from subsequent anemia with weakness, faintness, vertigo and headache. From the facts obtained from these studies Radtke concludes that in very many cases marked injury to health results from placenta prævia and that it is the duty of the physician to keep such patients under observation, and by examination, to determine the condition and combat any local or general disturbance according to the fundamental principles of gynecologic and medical therapeutics. In many cases it is possible to remove the objective changes resulting from placenta prævia, and not only improve their general condition and capacity to work, but also to contribute to the avoidance of abortion or premature delivery, or the repetition of placental anomalies. [w.k.]

Puerperal Eclampsia.—R. E. Skeel¹ thinks that the importance of the kidney as a factor in causing eclampsia has been overestimated. He reports a case in which there was not a trace of albumin in the urine before the first eclamptic convulsion. Almost complete suppression of urine followed the convulsion, and the small amount was loaded with albumin. Hence Skeel considers that the convulsive seizures gave rise to the renal lesions by the internal passive congestion which they produced. A multiplicity of factors seems to be concerned in

the production of eclampsia, varying greatly with different cases and different forms of the disease. Convulsions occurring before delivery almost invariably subside in a few hours after delivery, while those coming on after delivery vary from the very mild to the rapidly fatal and the treatment varies widely according to the form of the attacks. The antepartum convulsions, if severe, demand delivery, and any method which is necessary to relieve the mother is justifiable, when we consider the high proportion of cases which recover if delivery has been successfully effected. And his experience has convinced him that if vaginal examination shows a long, rigid cervix, which does not readily dilate, time should not be wasted in vain attempts at dilation, but that cesarean section should be at once performed. A table of 15 cases with treatment and results is given. [w.k.]

Condyloma Acuminata.—R. R. Smith¹ reports a case of abundant growth of condyloma acuminata in a female infant aged 19 months. There was no trace of syphilis, but the mother had had gonorrhea 9 months before the child was born. The growth extended well up on the mons veneris and backward an inch beyond the anus, involving both labia, was about 1½ inches in breadth, like a cauliflower in appearance, and hampered in color. Here and there were ecchymosed pinhead spots, evidently the seat of slight hemorrhage. The growth was entirely superficial and was clipped close to the base for its entire length, the hemorrhage being controlled with sponges and the cautery. Pointed condylomas in the female rarely attain the proportions here given. [w.k.]

Treatment of Postpartum Hemorrhage.—H. Fritsch² explains in detail 2 methods of treating postpartum hemorrhage according as it is due to atony of the uterus or to laceration. In the former the loss of blood may be the cause of the atony; and the blood which has gushed into the uterus must be quickly removed by pressure. Raise the uterus, place the hands posterior, press it strongly forward until the inner os uteri lies directly above the pubic bone. The space behind the uterus is filled with sponges or pads, so that the uterus remains pressed against the abdominal wall. Then either rolled bandages or towels knotted together are so applied as to keep the uterus in this position and render any collection of blood in the uterus impossible, as the inner walls are so pressed together that a cavity no longer exists. After 12 hours the bandage may be removed, as the vessels will then be closed by thrombus and the uterus may be restored to its normal position. When hemorrhage follows laceration, after removal of the placenta, he with the right hand presses the uterus as deep as possible into the pelvis, whereby all clots are pressed out, then with the left hand grasps the vulva, presses both labia firmly together, and in this manner exerts such pressure that the hemorrhage ceases. The position and technic of this procedure are fully described. The patient lies quite still during the half or three-quarters of an hour that the pressure is maintained, after which bleeding rarely returns. The advantages of this method are that the entire treatment is extravaginal, and excludes all danger of infection, and that this rational method of controlling hemorrhage is favorable to the early healing of the laceration. [w.k.]

The Influence of Fibromyoma in Pregnancy and Placental Formation as Well as in the Puerperium.—The dangers, says J. Nussbaum,³ that a fibromyoma brings to the pregnant woman, are not small. It may cause torsion of the pedicle with after-following gangrene with fatal results. Submucous fibroids produce a tendency to hemorrhage with severe anemia and interruption of pregnancy. The manifold pathologic changes of the placenta, and increased secretion, sometimes give rise to hydrorrhea of the gravid uterus. The firm adhesion of the placenta to the fibromyoma often observed, increases the difficulty of loosening the placenta and the danger of hemorrhage. This danger is also enhanced by the dilation of the bloodvessels, and by the fact that the presence of this neoplasm interferes with the contraction of the uterus. An infection of the myoma may also result in case a manual loosening of the placenta is necessary. Rubber gloves are

³ Wiener klinische-therapeutische Wochenschrift, January 3, 1904.

serviceable in such cases, also for removal of any placental remnants. Necrosis may ensue on the second day after delivery, usually later, and the necrosed portions show themselves in abundant lochia, fever, and other symptoms of sepsis. Abundant and oft-repeated irrigation of the uterus in necrosis of myoma is of more value than tamponade of the uterus. Of course all methods of treatment require on the part of the physician the utmost patience and care, in order to relieve such dangerous conditions and save the life of the patient. For internal treatment in checking hemorrhage in puerperium, dialysed secale cernutum is most valuable, and also tends to induce contraction of the uterus. [W.K.]

REVIEW OF LITERATURE

Therapeutic Value of the Serum of Truncceek.—Scheffler¹ reports 18 cases of various diseases in which he employed with good results this serum, which he claims is of distinct therapeutic value, despite the adverse criticisms of many writers. The site of choice for the injections is the buttock, the pain being very much less than in the arm or thigh. No untoward local or constitutional effect has been observed in more than 1,200 injections. The cases reported are types of the 80 which have been thus treated, and include neurasthenia, insomnia, dyspnea, pruritus, vertigo, etc. No effect is exerted on confirmed anatomic lesions. It is believed that the serum has an elective action upon the nerve centers, and thus upon general nutrition. The lessening of arterial pressure facilitates this action upon the nerve centers. Scheffler is now experimenting with a serum which he has devised, the preliminary results being very satisfactory. The composition of this serum is:

Sodium phosphate	3.23 gm. (50 gr.)
Potassium phosphate	0.60 gm. (9 gr.)
Potassium sulfate	0.45 gm. (7 gr.)
Sodium chlorid	9.70 gm. (23 dr.)
Distilled water	100.00 cc. (3½ oz.)

[A.G.E.]

Mineral Waters in Chronic Enlargement of the Spleen.

—According to Professor Kisch, the chronic enlargement of the spleen that remains after malarial fever, as well as the hypostatic enlargement of the spleen dependent upon circulatory disturbance or digestive disorders, and the like, responds favorably to drinking-cures with the sodium sulfate waters of Carlsbad, Marienbad, Tarasp, and Rohitsch, in connection with which an after-cure with pure ferruginous waters is necessary in order to improve the disturbed hemogenesis. As the most efficient adjuvant to bring about reduction in the size of existing enlargement of the spleen, and to improve the anemic and the leukemic state of the blood, the use of the peat baths containing the greatest quantity of iron sulfate at Marienbad, Franzensbad, Elster, Meinberg, and Muskau is highly recommended. If the enlargement of the spleen is one of the manifestations of a constitutional disorder, such as syphilis or mercurial cachexia, the sulfurous waters, especially of Aachen and Baden in Austria, and the iodine waters, as for instance those at Hall, Kreuznach, Krankenheil, and Lippik, are indicated; brine baths and sulfurous baths being employed in addition. The enlargement of the spleen that occurs in scrofulous and rachitic individuals is favorably influenced by drinking-cures at Kissingen, Homburg, Nauheim, Kreuznach, Baden-Baden, and Wiesbaden; and by the employment of the baths provided at these resorts. Hinsdale mentions among suitable resorts and waters in the United States those of Saratoga, Sharon, Richfield, and Glen Springs in New York; Roanoke Red Sulfur Springs in Virginia; Parkersburg Mineral Well in West Virginia; Ypsilanti and Mt. Clemens in Michigan; Calistoga Hot Springs and Coronado Springs in California; Tampa Spring at Glenwood, Colorado; and Lower Blue Lick Springs in Kentucky.—[System Physiologic Therapeutics, Vol. ix.]

¹ La Médecine Moderne, December 23, 1903.

Therapeutic Management of Febrile Diseases in Children.—A. Caillé¹ states that in children the important points in the management of acute febrile diseases are diet, hydrotherapy, rational stimulation, and free breathing of pure cool air. Drugs are useful occasionally, but they no longer dominate therapeutics. After the bowels have been made to move, drugs are not indicated unless for some special and substantial reason. The more intelligent have lost faith in drugging, and medical men should not countenance or encourage superstition or credulity in drugs. When a placebo seems indicated, the administration of a few drops of dilute hydrochloric acid in sugar water is rational and does no harm. [A.G.E.]

The Use of Ichthyol in Tuberculosis.—Spangler² speaks very highly of the value of the internal use of ichthyol in tuberculosis. In order to get good results it is wise to give the drug in ascending doses. The disagreeable taste and eructations may be largely overcome by giving the drug in capsules. The method he employs is to have the patient begin with No. 1 empty capsule, which he himself fills with ichthyol, taking one after each meal for the first week, adding another to each dose during the second week, and 3 such capsules in the third week, 3 times a day. If discomfort arise from eructations it is a sign that the stomach is not appropriating the full amount of ichthyol, and the period between the administrations should be lengthened. [H.C.W.]

Theobromin as a Hypnotic.—L. Gallavardin and M. Péhu³ have obtained very satisfactory results from the use of theobromin in the insomnia accompanying certain cardiac or vascular lesions. It is especially efficacious in the affections called arterial, that is, in which the cardiac lesion is due to or accompanied by atheroma of the aorta, syphilitic aortitis, etc. Minimal doses generally suffice, from 1 cachet to 4 cachets of 8 gr. (50 cg.) each, given during the afternoon or evening. The drug is believed to have a particular action on the cerebral tissues in these cases. [A.G.E.]

The Treatment of Seasickness.—S. Solis Cohen⁴ recommends as a preventive of seasickness that all work, so far as possible, be avoided for 24 hours before embarking, so that the system may not be exhausted, and as hearty a meal as possible be eaten before going on board. A calomel purge, followed by saline should be used 1 week before sailing, and again 2 days before. Saline laxatives or enemas should be used daily for the first few days on shipboard. As much time as possible should be spent on deck, if necessary, in a reclining position. Light, easily digested foods should be taken at frequent intervals. Strychnin, atropin—or better, picrotoxin, may be given in small, frequent doses for a few days before sailing, and continued until sea legs are gained. Beside this, he believes that the use of epinephrin (suprarenalin) in doses of 3 mg. to 5 mg. ($\frac{1}{4}$ gr. to $\frac{1}{2}$ gr.), dropped on the tongue, is useful in some cases. After onset of the naupathia, the patient should take small amounts of light foods, such as soups, junket, beef juice, peptone and the like at short intervals. Many experienced ship surgeons prefer solid food when possible to get patients to take it. Effervescent drinks, as dry champagne, seltzer, etc., are frequently beneficial. Counterirritation over the epigastrium is highly recommended. The Winternitz combination compress, which consists of a cool compress enclosing a warm epigastric coil has been found of value in other forms of vomiting, and should be of benefit, if available. Outside of the laxatives, the drugs which have been recommended are the bromids, chloral, and other hypnotics. Cohen has seen benefit only from the bromids and occasionally from morphin. The vasomotor stimulant effects of cocain, strychnin, and atropin have been lauded by many authors, and are frequently of use. [H.C.W.]

The Treatment of Emphysema.—Bjorkman⁵ does not believe that any permanent benefit is gained in emphysema by the use of drugs or by the use of ordinary pneumatotherapy. The best method of treatment consists in making firm pressure with the hand on the lower part of the chest during expiration,

¹ The Postgraduate, December, 1903.

² Proceedings of the Philadelphia County Medical Society, Vol. xxii, p. 357.

³ Lyon Medical, November 8, 1903.

⁴ Reference Handbook of the Medical Sciences, Vol. vii, p. 82.

⁵ Merck's Archives, 1903, Vol. v, 369.

the patient keeping the glottis open by a prolonged ah, which treatment should last from 5 to 10 minutes, and be repeated daily. Pneumatotherapy may give temporary relief, but its benefits are usually not permanent. Drugs are useful to relieve accompanying catarrh. [H.C.W.] [Bjorkman is wrong. Pneumatotherapy is permanently useful, although it does not restore lost alveolar septa. s.s.c.]

The Use of Electricity for Urethral Stricture.—O'Neill¹ asserts that the treatment of urethral and other strictures by electrolysis is unjustifiable, since any current which is strong enough to have a distinct action and carry away scar tissue will leave a scar behind it. This he has demonstrated experimentally on external scars. Attempts to remove them by electric treatment has invariably led to destruction of the tissue and healing by granulation. The application of electric currents of 2 milliamperes to the mucous membrane of the mouth led to sloughing of the part and the reparative process required 7 days for its completion. He has seen a number of cases of urethral strictures in which much harm was done by the use of strong electric currents. Electrocautery incisions are equivalent to internal urethrotomy, excepting that the scar must slough off before healthy granulation can take place. [H.C.W.] [Which simply means that plumbers are not watch-makers.—s.s.c.]

NERVOUS AND MENTAL DISEASES

J. K. MITCHELL

F. SAVARY PEARCE

EDITORIAL COMMENT

Fatal Termination of Chorea.—The prognosis of chorea has of recent years been exercising the clinical wits of many of the foremost physicians, as its pathology has never ceased to do from the dawn of its history down to the present date. The early authorities on this interesting disease (Sydenham, Sauvage, and Bouteille de Manosque) did not seem to recognize the possibility of a fatal termination. In their experience it would appear to have nearly always ended in a complete recovery; and the unfavorable sequence was represented by one or more relapses or by transition to the chronic state. So far as we can trace, a fatal ending of this disease was first placed on record by Pretchard in 1825. He attributed the untoward result to some (undetermined) medullary lesion. In 1831, Courtois described the symptoms which ushered in the fatal termination; and this was again discussed (in 1833) by Ieanjacquet, who collected and discussed all the cases which he had found previously reported. Since that date every author of note who has examined the subject of chorea has recognized such results, and discussed them with more or less luminosity. With regard to the cause, it may be said that although an almost endless series of lesions have in turn been reported as causative or coincident, their existence and the theoretic consequences therefrom deduced have proved on critical examination to be so various and so irreconcilable, both as to their seat and their nature, as to be bewildering rather than instructive. Here are the principal ones; and by a glance at their enumeration every intelligent reader can, without possessing the advantages of the special pathologist, judge for himself how much scientific certainty can be created from the elements of such an anatomic chaos: Calcareous patches of the cerebellum (Bazin); of the choroid plexus (Boscredon); of the general pia mater (Frank); of the centrum ovale (Brown); of the cerebrum (Guersant); acute meningitis of the convexities of the hemispheres (de Beauvais); ossification of the cerebral pia mater (Fargues); formation of false membranes on the surface of the hemispheres (Semmering, Lélut); atrophy of the convolutions, with sclerosis of the grey matter (Meynert); induration and hypertrophy of the medulla oblongata and medulla spinalis (Bergeon, Hutin); lesions of the tubercula quadrigemina (Puccinotti, Serres). One item of judicial concession must however be granted be-

fore pronouncing sentence collectively on the purveyors of the materials of this pathologic chaos. It is this: That till comparatively recent years the purposeless and incoordinate movements of chorea were confounded with those of various phases of hysteria, of tetany, of "electric" chorea, of Jacksonian epilepsy, of Huntington's disease, of Charcot's disease, of paralysis agitans, of myoclonus, and of other conditions in which symptomatic incoordination of muscular movements happened to be present. Some such cases have, as might be expected, displayed lesions in the neighborhood of, or actually involving, the nerve bundles of which structural alteration produces, hemichorea (as Charcot and Raymond have shown). Dr. Vicq¹ has recently collected a vast mass of evidence on the subject of fatal chorea, and finds that the lesions found are usually of the congestive type. Those may be either localized or diffused; comparatively slight, or so intense as to have gone on to the production of extravasation (intracranial or intraspinal hemorrhage). In fact hyperemia—meningeal, meningo-encephalic, and meningomedullary—is the pathologic condition which usually determines the fatal issue in this class of cases. Still the idea that such lesions are the essential causes of true chorea is sharply controverted by Dr. Vicq. It is admitted by all, that corresponding local hyperemias are found in cases in which no choreic symptoms have presented themselves during life. On the other hand, reports of pathologic examinations of fatal cases of chorea have been published by the most reliable authorities (e.g. Barrier, Bright, Damaschind, Charcot, Dufossé, Denegès, Gerhardt, Gombault, Grisolle, Quinon, Hache, Heokin, Maynier, Ollivier, etc.) in which the most minute scrutiny of the nervous system failed to detect even a microscopic lesion. So that up to the present date we find ourselves in the humiliating position of being obliged to admit that the primary cause of chorea still remains a mystery. Even the attractive "embolic" theory of Kirkes and Hughlings Jackson has ceased to retain the confidence of scientific pathologists. So that an unoccupied niche in the temple of (pathologic) Fame stands ready for the successful solver of this sphinx-like problem.

Cerebral Rheumatism.—As our readers are doubtless aware, the clinical entity of cerebral rheumatism was for the first time definitely recognized by the great French physician, Trousseau. His description of its characteristic phenomena still remains a classic in the literature of medicine. But the means of examination at his disposal did not enable him to recognize any of the structural changes which accompany its development and progress. And ever since his time, comparatively little has been written on the subject, for till quite recently a practical technic had not been elaborated which could enable the pathologist to throw any new light on the intimate nature of the condition. But we are pleased to note that in Paris, the city which witnessed its discovery, a report has just been made which illuminates its nature. At the meeting of the *Société Médicale des Hôpitaux* on October 16, M. Iosué and M. Solomon described the results of the postmortem examination of a fatal case of a woman 38 years of age. Her illness began with sore throat, 4 days before her admission to hospital; soon after the feet became painful, and the joint affections rapidly extended to the knees, hips, wrists, elbows, and shoulders. Also violent headache developed, and abundant perspiration appeared. On admission to hospital the face was flushed, and the pupils contracted. There were jerky contractions of the muscles of expression; also of the muscles of the limbs. She was completely delirious. The articulation of both feet, and of the right knee, left elbow and wrist were distinctly swollen, and the overlying skin was hot. On the following morning the temperature was 102.5° F.; in

¹ American Electrotherapeutic and X-ray Era, July, 1903, p. 239.

¹ These de Paris, 1903, I. Rousset.

the evening it was 104.5°. There was no cardiac murmur, but the sounds were muffled. There was disproportionate dyspnea, as the only pulmonary signs were some subcrepitant rales at the bases of the lungs. There was a trace of albumin in the urine. Sodium salicylate was administered, and on the next day the evening temperature was a degree lower (103.5°), but the delirium persisted. Next day but one, the delirium was less pronounced, but the face was cyanotic and there were pronounced bronchitic rales over both pulmonary areas. On the following day the patient became violent, and restraint was necessary to prevent her getting out of bed. Death occurred in the night. An autopsy was made. There was no increase of cerebrospinal fluid, but the brain was intensely congested, especially on the basic aspect and throughout the frontal lobes. The lungs were congested and edematous in the basic segments. There were some filamentous pleural adhesions. There was no endocarditis, but some gelatinous patches were found at the origin of the aorta, around the orifices of the coronary arteries. The right knee-joint contained a considerable quantity of a thick, cloudy fluid. The brain was examined with special care. Sections of the frontal lobe and of the motor region were stained according to Nissl's method. The meninges over the frontal lobe showed no evidence of leukocyte infiltration. But the nerve cells had undergone profound alteration. The chromatophile granules had entirely disappeared. The achromatic substance displayed a uniform tint, with a granular appearance and a tendency to "fragment." Some of the cells were fissured. The nuclei were stained with more than normal vividness. "Neurophagia" was observed in many of the sections. Some cells had been attacked by 2 or 3 "neurophages," which had excavated a kind of notch in the side of the affected cell. In others, the whole of the protoplasm had disappeared, leaving only the nucleus with one or more neurophages in a vacuole; and in some instances the cell had been completely destroyed, leaving but a mass of neurophages in a clear space. The neurophages themselves presented 2 varieties: Some were like macrophages, and had a large, clear nucleus; the others had but a small nucleus, and displayed some resemblance to lymphocytes. In the motor area of the brain the meninges gave a mononuclear leukocytic reaction. The changes in the nerve cells showed some difference from those which had taken place in the cells of the frontal lobe. The cells had been less affected, and there were fewer neurophages present in proportion. Large diplococci and bacilli were found in the vessels of the pia mater, which took kindly to Gram's stain. There were also diplococci in the pia mater, and in some of the capillaries of the cerebral substance. The result of this report is an important item of pathologic enlightenment on the subject of an interesting and previously very obscure series of clinical phenomena. The intensely marked microscopic lesions certainly display a curious contrast to the trivial macroscopic ones.

Responsibility and Crime.—No more difficult problem in medical jurisprudence exists for us than the conscientious determination of responsibility of the accused in acts of criminality. There are those who on one extreme would have it that most criminals are mentally diseased—a gross exaggeration. In law, if a man can be proved sane on acts which are criminal, he is given "just" punishment even if he is insane on other subjects. To our mind psychopathy is often engendered by passions permitted to run riot, and if such can be proved to be the malicious will of the later developed moral pervert (there being no frank insanity), he is, in our judgment, a responsible agent for his crime, and justice is subverted by his punishment. Beside the moral lesson to contemporary criminals of like stamp is thus enormously accentuated; punishment will tend,

more than anything else, to bring them into the paths of rectitude. The late Herbert Spencer believed in the progressive evolution that *knew* the mind of man was increased in breadth by education. Progeny of such held the better or worse "plate" upon which were more or less easily registered impressions. Given a healthy brain ("plate"), if the subject does not develop it properly it is his own default, and the "black sheep" of a family often has his parents to blame in forcing upon him a poor plate; while he is "responsible" in the measure that he develops the moral qualities of his mind.

REVIEW OF LITERATURE

Local Panatropy.—W. R. Gowers¹ applies this name to a curious affection as a fitting designation. There are quite universal atrophic patches upon the trunk, limbs, or face, which vary in diameter from that of a nut to that of an orange, or larger. There seems to be wasting of all subcutaneous tissues down to the bones, with slight change also in the skin, which is there distinctly thinner and slightly discolored. The aspect of the areas may be described as that of a subcutaneous excavation. The patches are distributed quite irregularly without apparent relation to the muscles or to the nerve distribution. When the wasting is considerable, the muscles are much affected but never entirely disappear, but the electric irritability remains always normal. There may be implication of bones. It may be in relation to facial hemiatrophy, but no definite pathologic changes have been determined. [The name of this disease describes a distinct clinical entity.]

A Case of Pathologic Sleep in a Hysteric Subject.—Serge Soukhanoff² reports this instructive case, and concludes after noting several long instances of sleeping (one of 38 hours) in the patient, that the pathologic sleep had two morbid elements: 1. The patient unconsciously tried to isolate herself from outside impressions; this she did under the influence of mystic delusional ideas. The latter could easily be compared to those induced by toxic doses of hashish. 2. There was a distinct hysteric phase of the disease, since the patient showed hysteric tendencies during the course as well as before the onset. [Such a case as this recorded in the lay journals has proved to be *bona fide*.]

Treatment of Early Mental Cases in a General Hospital.—M. Springthorpe³ makes a plea for early and doubtful cases of alienation, also the separation of curable cases in small wards or detached hospitals. The author has treated some of his insane patients in wards of the Melbourne Hospital, and arrives at the conclusion that early cases and mild forms of mental diseases are better so treated than in State asylums.

Microscopic Adolescent Survivals in Art, Literature, and Pseudoethics.—James G. Kiernan⁴ goes over this comprehensive subject in a paper to be continued. "At puberty, according to Lombroso, exaltation flings the nervous system into turmoil, fatal to weakness, but raising strength to a vertiginous height, because at this complete organism transformation, psychic centers suffer." These phenomena are transitory among normal being, but occurs in a large scale in geniuses, and the mentally morbid. "Impressions received by sexual psychopaths during puberty thereafter tinge mentality." An analytic study of even the above short abstract of the subject will be a source of help to the psychologist who hopes to prove of some value in practical sociology. The baneful effect upon pubescent youth of the land in recent lynchings is a sad blow to moral progress.

Diagnosis and Operative Treatment of Meningeal Tumors of the Spinal Cord.—F. Schultze⁵ reports 11 cases of extramedullary tumors of the spinal cord. The diagnosis was made with considerable certainty in 8 cases. The diagnosis between meningeal tumor and chronic meningitis is sometimes difficult, especially if tumor-like thickening of the membranes

¹ Review of Neurology and Psychiatry, January, 1903.

² Journal of Mental Pathology, October and November, 1902.

³ Intercolonial Medical Journal of Australia, April 20, 1903.

⁴ Alienist and Neurologist, May, 1903.

⁵ Mitt. a. d. Grenzgeb. d. Med. und Chirurg, Bd. xii, p. 153.

occurs. Intramedullary tumor may be diagnosed by the absence of neuralgic premonitory symptoms, and by the early development of sensory disturbances, especially a dissociation of sensations. Compression by disease of the vertebrae must also be excluded. The upper limits of the tumor may be determined frequently by a zone of hyperesthesia lying above the hyperesthetic area. The extent of the tumor is often difficult or impossible to determine. Extramedullary tumor may be diagnosed with considerable certainty, if syphilis and myelitis be excluded, by a permanent and progressive motor and sensory paralysis, whose upper limit remains nearly constant. Seven of the reported cases were subjected to operation, of which 3 were cured, and 1 received considerable improvement. [B.K.]

Tabes and Trauma.—Windscheid¹ discusses the importance of a possible traumatic origin of tabes and the opinion concerning the causes of the disease. In 70% lues is proved; the remainder is explained by cold, overexertion, sexual excesses, and trauma. Whether trauma is capable of producing similar lesions cannot positively be denied, as the pathologic and functional results of traumatism are unknown to us. The insults of trauma are divided into 3 groups depending upon the portion of the body affected—the back, the head, the peripheral nerves. The production of tabes from trauma may possibly be explained by action on peripheral nerves but not against the other 2 portions; it used to be taught that trauma may produce neuritis, and this ascending may produce tabes, but recent investigations have proved that only the spinal ganglia, posterior roots and columns degenerate, and the peripheral nerves escape. Trauma may produce the disease as syphilis does, through the formation of toxin. As tabes in so many cases has such an insidious onset and course, it cannot be proved that trauma is the cause; the chances are that before the trauma a latent tabes existed, which was made manifest by the injury. The trauma is probably capable of giving an impetus to the disease. [E.L.]

Amyotrophic Lateral Sclerosis.—Joseph Collins² states that amyotrophic lateral sclerosis is among the rarest of all organic nervous diseases. In his clinic the diagnosis has been made 6 times in 5 years, during which time about 7,000 new cases of nervous diseases have been under observation. Six or 7 cases have been seen in 10 years at the City Hospital. Collins gives in detail the clinical, autopsy, and histopathologic notes of a case occurring in a woman of 38. This is followed by a general consideration of the subject, during which he states that it is impossible to settle positively, from histologic study of these cases, the disputed point as to whether the peripheral or central neuron is first affected. Probably it is the former in some cases, the latter in others. Because of cases like the one reported by Collins, it must be admitted that the lesion in some instances begins in the cells of the anterior horn, and that destruction of those cells causes at least part of the phenomena of the disease. The spasticity and exaggerated reflexes are to be explained by an alteration in the central motor neuron in the brain. Collins freely admits that the lesion of amyotrophic lateral sclerosis is often, perhaps always, if the disease lasts long enough, a degeneration of both systems of neurons throughout their entire course. His contention is that such involvement is not necessary for the existence of the disease clinically. Regarding the etiology of the disease, Collins is unable to contribute anything. The pathologic chemist is not unlikely the one who must solve that problem. A statistical study of 104 cases is appended. [A.G.E.]

Changes in the Spinal Cord after Loss of An Extremity.—Q. Mathyas³ reports 2 cases. In Case I the left lower extremity was amputated at the middle of the leg, seven years before death. The spinal cord showed atrophy of the left posterior column and left anterior horn, most marked in the lumbar region; also slight ascending degeneration of Goll's column on the left side, most marked in the cervical region. The cauda equina and the column of Clark on the left side also showed atrophy. In Case II the left leg was amputated 3 months

before death, and the left arm in its lower third 4 years previously. In this case the spinal cord showed atrophy of the left anterior horn in the lumbar, upper dorsal and cervical parts, and ascending degeneration of Goll's tract in its anterior two-thirds; also atrophy of Burdach's column on the left side, beginning at the third dorsal segment, and being almost complete at the sixth cervical, above which it again diminishes. The cauda equina and Clark's column on the left were also affected here. The changes in the posterior column are to be regarded as atrophy of disuse. Those in the anterior horn are due to secondary changes of nutrition and function that occur in the ganglion cells, following section of their nerve fibers and consequent loss of function. [B.K.]

Brachial Neuralgia.—Robert M. Simon¹ states that neuralgic pains affecting some branches of the brachial plexus are common in aneurysm, cancerous growths in the thorax or axilla and in aortic disease, but brachial neuralgia not symptomatic of these conditions is rare, and is of such extremely painful nature as to demand the more than slight attention which it receives. He reports several cases which he regards as typical, and he believes that the condition is usually due to traumatism or strain which causes a perineuritis, and he appears to lean to the view that the condition is not truly neuralgic, but a painful neuritis and perineuritis. The essential points in a typical case are recited. A woman of 45 fell from a tram car; she was stunned, but quickly recovered, and was unconscious, having sustained injury. In a week she began to suffer from pain in both arms along the distribution of the brachial plexus, and there some tenderness about both shoulders. This was followed by increasing pain and tenderness, especially on moving the arm and great loss of power in both hands and arms, and some muscular wasting. It was thought she had sustained spinal injury, and she claimed compensation from the tram company. Simon was called to see her, and believed it was simply a painful condition from pressing muscles caused by the fall, and that the nervous symptoms were due to secondary perineuritis and pressure on the branches of the brachial plexus, which proved to be true, and under rest the patient made a complete recovery. [A.B.C.]

Compulsory Movements in Localized Lesions of the Brain.—W. A. Muratow² makes an exhaustive analysis of literary data, and of several original observations concerning involuntary movements in cerebral lesions. He sums up as follows: 1. Compulsory movements are dependent on destruction of the connecting cerebellar crura. This is proved by his data with all requisite scientific strictness. 2. The existence of an independent sensory tract in the internal capsule is doubtful. 3. The theory of a cortical origin of convulsive movements must be abandoned, because the clinical picture of cortical convulsions is different from athetosis and chorea, and because there is no anatomic basis for the theory. 4. While the convulsive disorders are thus seen to have a subcortical origin, we may admit a reflex influence on the cortex and the pyramidal tracts. This will explain the motor disturbances observed after lesions of the optic thalamus. [L.J.]

Landry's Paralysis.—Rolly,³ basing his observations on the study of 7 cases, considers Landry's paralysis an acute polyneuritis, and not a disease *sui generis*; in 5 of his cases the neuritis was positively demonstrated; in the other 2 the study could not be made sufficiently complete. In addition to the pathologic identity he also found many clinical resemblances, and the 2 points of difference (the preservation of certain groups of muscles in neuritis and the method of attack, which in Landry's paralysis is ascending, affecting all the muscles quickly, and in neuritis jumps from one group to another with possible intervals of days or weeks) are insufficient in his opinion, to separate the 2 diseases. He feels certain that if in all cases careful histologic examinations are made, neuritis will always be discovered. [E.L.]

The Fasciculus of Türk.—Pierre Marie and G. Guillian⁴ contribute a lengthy article, containing 21 illustrations, to

¹ Münchener medizinische Wochenschrift, June 30, 1903.

² American Journal of the Medical Sciences, June, 1903.

³ Zeitschrift für Heilkunde, 1903, Bd. xxiv, Heft 1, Abth. f. Path., Heft 1, p. 14.

¹ British Medical Journal, July 11, 1903.

³ Münchener medizinische Wochenschrift, Nos. 30 and 31, 1903.

⁴ La Semaine Médicale, July 15, 1903.

the study of the origin and degeneration of this fasciculus. They have made a histologic study of 19 cases which they briefly detail. They believe their statistics to be the most important contribution, either in France or in other countries, to the anatomy of the nervous system. Their cases prove that the fasciculus of Türek is a descending fasciculus, and not, as was for a long time held, a sensory ascending tract. The facts adduced by them show that the fasciculus degenerates from above downward, following cortical and central lesions. It is true that this degeneration is more rare than that of the pyramidal tract. They give a scheme showing the site of the lesion most often leading to degeneration of the fasciculus in question. This is situated between the temporal convolutions and the external wall of the occipital cornua of the lateral ventricle. They believe that the fibers of this fasciculus arise, for the greater part at least, in the third temporal convolution, as in several cases of involvement of the first and second convolutions degeneration did not follow. The writers admit their ignorance of the function of the fasciculus of Türek. [A.G.E.]

The Problem of Insanity in Ireland.—W. R. MacDermott¹ recalls the immunity of Ireland from insanity in the first half of the last century. The age of predisposition is from 25 to 60. Those below 25 are relatively free. Whatever character the individual may possess it is confirmed by age and more capable of transmission. The Irish population in the first half of the century was, to a considerable extent, the offspring of young and now in increasing degree of elderly parents. Under the stress of economic conditions prevailing between 1841 and 1851, the sum of nonprolific individuals had an immense advantage over the general mass encumbered with a heavy burden of child life. The survivals were either unmarried, or with small families, in general elderly, and with determined habit of life. Not in Ireland alone but all over western Europe increase of insanity is peculiarly a phenomenon of agrarian life effected by diminution in the unstable mass of laborers, leaving the stable class proportionately larger. In general the heads of families are of mature age and the custom of primogeniture selects the eldest to perpetuate the family. [H.M.]

Changes in the Spinal Cord in Diphtheric and Alcoholic Paralysis.—J. M. Clarke² reports a case of paralysis of all 4 extremities, of the diaphragm, and with bronchitis. Abundant virulent diphtheria bacilli were found in the throat, but absolutely no local lesion had occurred. At necropsy degenerative changes were found in the cells of the anterior horn and their extensions, also in the cells of Clarke's column, and in the afferent fibers of the posterior roots and posterior columns. A second case of alcoholic paraplegia is also mentioned, in which similar degenerative changes were found in the cells of the anterior horns in the lumbar region. [B.K.]

Babinski's Toe Reflex.—A. Richter³ has studied the phenomenon on 500 individuals with probably normal pyramidal tracts. In 9 of these (1.8%) a positive Babinski phenomenon was noted, indicating that the symptom possesses a high, although not absolutely pathognomonic value. [E.L.]

History of a Case of Cerebral Tumor Eight Years after Removal.—Thomas Oliver⁴ reports that 8 years ago Mr. Williamson removed an angioma from the motor area of the left side of the brain in a patient who was then 23 years old. Following the operation it was noticed that she had lost power of speech; she could say yes and no but often used them incorrectly. Otherwise the patient was in good condition except that there was paralysis of the right hand and arm and paresis of the right side of the face and the right leg. By degrees she gradually recovered the use of the right side of her body, but her speech was very defective, though she understood all that was said to her. In the intervening years her speech has gradually improved though it is yet somewhat defective. There is still considerable loss of power in the right hand and forearm. The fingers are firmly flexed on the palm of the hand, there is well-marked wrist and knee-jerk which is explained by the descending degeneration caused by the tumor itself and subsequently by the operation having destroyed the

cortical centers. Though the power of speech has not been fully regained yet, the recovery has been very considerable. The recovery may be due to improved nutrition of the remnant of speech center in the left side of the brain that escaped injury at the operation, or it may be that the right cerebral hemisphere has undertaken the function of speech through education, an assumption to which the patient, by cultivating the use of the left hand in writing, may have contributed. [A.B.C.]

Antirabic Inoculation and Nervous Disease.—There are reports in literature of spinal disease following Pasteur's inoculation in persons bitten by mad dogs. T. K. Chmielewski and F. F. Skshivan¹ had occasion to observe closely two such instances. The nervous symptoms were chiefly those of spinal meningomyelitis. The entire affection resembled an acute infectious disease, there being fever, respiratory difficulty, facial and ocular palsies. The duration is $\frac{1}{2}$ to 2 months. Recovery always takes place. The clinical picture corresponds closely to that of paralytic rabies in man, and the authors are strongly inclined to consider the peculiar symptom-complex as a benign form of paralytic rabies, weakened by antirabic inoculations. [L.J.]

Infantile Paranoia.—Heinrich Schlöss² describes a case of paranoia occurring in a boy 8 years old. Aside from the fact that his brother had killed himself in his sixteenth year, there was no history of psychosis or neuroses. At 4 years of age he suffered from laryngismus stridulus, from which, together with an early use of alcohol and masturbation, his brain had suffered. His grandfather, who cared for him, had been extreme in his disciplinary measures in the child's early youth, and, furthermore, at the age of 8 years he was sent to an educational institution. His record in the school was for distinct ethical defect. He was idle and obdurate. He would steal, lie, was insulting, and had no regard for religious matters. He was also inclined to the use of alcohol. This conduct might in part have been due to hallucinations. He was extravagant, and had the hallucination that water had an offensive odor, and, therefore, refused with great excitement to bathe. His peculiarities regarding his food at the age of 8 years, clearly indicated the presence of delusions. At 12 years of age he insisted in changing his food with that of another boy, and only ate after it had been previously tasted by the caretaker. He developed delusions of persecution; he feared the anarchists who only kill the rich; his food was poisoned; his wash-water smelt of urine; his food was mixed with urine and filth; his companions gave him no rest. At night he saw persons that scoffed at him and laughed. He gradually grew worse, until he was unable to make any progress with his studies. The interest in this case centers in the fact that delusion occurred at such an unusually early age. [J.H.W.R.]

Multiple Sarcomatosis of the Central Nervous System.—W. G. Spiller and W. P. Hendrickson³ report 2 cases of this affection and one of intramedullary primary sarcoma of the spinal cord. The first patient was a woman of 21. Two intramedullary sarcomas were found in the thoracic region of the spinal cord, and numerous small tumors in the spinal pia. A large sarcoma was found in the left cerebellar lobe. The second patient was a man of 42, on whom an unsuccessful attempt was made to remove a supposed cerebellar tumor. At autopsy a tumor was found in each cerebellopontile angle, about the gasserian ganglia, pituitary body, floor of the fourth ventricle, right internal auditory meatus, and right jugular foramen. Numerous small tumors were also found in the pia of the spinal cord. The third patient was a man of 39, in whom a primary sarcoma was found within the spinal cord just above the midthoracic region. Full clinical and autopsy notes of the 3 cases are given. Spiller dwells at length upon the diagnosis of sarcomatosis of the brain and cord, saying that it may cause great difficulty, and in some cases even be impossible. This is partly because of the escape of the nervous tissue in many cases. An incorrect diagnosis of syphilis is not unlikely. Sarcomatosis may also give the signs of tuberculous meningitis. The occurrence of a cerebellar tumor in so many of the recorded cases of sarcomatosis of the central nervous system is consid-

ered to be remarkable. The possibility of operative treatment is discussed. Spiller does not believe that an encapsulated tumor of the spinal cord can be removed with much benefit to the patient. [A.G.E.]

Brain Affections Following Carbon Monoxid Poisoning.—C. Sibelius¹ reports the case of a young man who, after 5 minutes' exposure to carbon monoxid gas, remained unconscious for a day. On awaking he was totally blind. A few days later fever set in, with cramps, loss of consciousness, twitchings, dilated and immobile pupils. The patient again recovered consciousness, but showed signs of extensive cerebral involvement until his death, 3 months later. These symptoms were paralyzes in various parts of the body, hallucinations, bedsores, epileptiform attacks, and dementia. A complete pathologic examination was made after death, especially of the brain. In the latter were found degenerative changes in the bloodvessels, with consequent multiple hemorrhages; also multiple degenerations and softenings of the gray substance, irregular degenerations of nerve fibers, and increase in neuroglia. The changes in the bloodvessels in many places led to thickening of their walls, the latter causing ischemia of the brain substance, with resulting softenings. All of the degenerative changes in the nerve elements, however, cannot be attributed to this ischemia alone, but must in part be ascribed to the direct influence of the CO, and also to the hemorrhages. The various important and peculiar symptoms are discussed and explained pathologically. A bibliography is appended. [B.K.]

THE PUBLIC SERVICE

Health Reports.—The following cases of smallpox, yellow fever, cholera and plague, have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended February 5, 1904:

SMALLPOX—UNITED STATES.			Cases	Deaths
District of Columbia:	Washington.....	Jan. 23-30.....	1

Changes in the Medical Corps of the U. S. Army for the week ended February 6, 1904:

STUCKEY, HARRISON W., contract surgeon, is granted leave for two months, on account of sickness, with permission to visit Japan.

WELLS, FRANCIS M., contract surgeon, is granted leave for two months, with permission to visit the United States, and with authority to apply for an extension of two months.

ALLEN, IRA A., contract surgeon, is granted leave for two months, with permission to visit the United States.

UNDERWOOD, FRED R., contract surgeon, will proceed to his home, London, Ohio, for annulment of contract.

JORDAN, EDWARD H., contract surgeon, is relieved from further duty with the Twenty-eighth Infantry, Infantry Cantonment, Presidio, and will proceed to his home, Denver, Col., for annulment of contract.

STONE, FRANK P., contract dental surgeon, will proceed to the Presidio for duty, relieving Contract Dental Surgeon William G. Hammond.

HENRY, JOSEPH N., contract surgeon, now at Philadelphia, Pa., will proceed to Fort Slocum for duty.

OHLINGER, LORIN B., contract surgeon, is granted leave for one month, on account of sickness.

MURRAY, First Lieutenant ALEXANDER, assistant surgeon, is assigned to duty as surgeon on the United States transport Sheridan, to take effect upon the arrival of that transport at Manila, P. I., relieving First Lieutenant John W. Hanner, assistant surgeon. Lieutenant Hanner will report to the commanding general, Philippine Division, for assignment to duty.

APPEL, Major AARON H., surgeon, extension of leave on surgeon's certificate granted November 28, is extended three months.

BURKHART, JOHN., contract surgeon, now at Grand Rapids, Mich., will proceed to San Francisco, Cal., and report for transportation to Philippine Islands.

BARBER, ERNEST C. A., sergeant first class, Military Hospital, Pumping Station, Rizal Province, P. I., will proceed to San Francisco, Cal., for orders.

Changes in the Medical Corps of the U. S. Navy for the week ended February 6, 1904:

STRINE, H. F., assistant surgeon, detached from the Naval Station, Isabela, P. I., and ordered to the Navy Yard, Olongapo, P. I.—January 30.

CRANWELL, A. G., surgeon, granted sick leave for three months from February 2—February 2.

HEIMER, R. G., assistant surgeon, ordered to the Naval Hospital, New York—February 2.

STOOP, R. E., assistant surgeon, ordered to the Naval Hospital, Norfolk, Va.—February 2.

SPEAR, R., and SHIP, E. M., surgeons, commissioned surgeons from March 3, 1903—February 2.

MORSE, E. T., pharmacist, detached from the Naval Laboratory, February 21, and ordered to the Naval Station, Cavite, P. I.—February 2.

Changes in the Public Health and Marine-Hospital Service for the week ended February 4, 1904:

WARREN, B. S., assistant surgeon, granted leave of absence for seven days from February 12—February 3, 1904.

FOSTER, S. B., acting assistant surgeon, department letter granting Acting Assistant Surgeon Foster leave of absence for ten days from January 17, 1904, amended to read ten days from January 21—February 3, 1904.

MAGUIRE, E. S., pharmacist, relieved from duty at Fort Stanton, N. M., and directed to proceed to Mobile, Ala., and report to medical officer in command for duty and assignment to quarters, relieving Pharmacist J. E. Beck—February 1, 1904.

BECK, J. E., pharmacist, upon being relieved from duty at Mobile, Ala., by Pharmacist E. S. Maguire, to proceed to Fort Stanton, N. M., and report to medical officer in command for duty and assignment to quarters—February 1, 1904.

HOLT, E. M., pharmacist, granted leave of absence for twenty-seven days from January 1, 1904, on account of sickness—February 3, 1904.

Promotion.

ROBINSON, D. E., assistant surgeon, commissioned as passed assistant surgeon, to rank as such from December 28—January 28, 1904.

Appointment.

FOSTER, WILLIAM J., appointed acting assistant surgeon at Lexington, Mich., for examination of keepers and surfmen of the Life Saving Service—January 27, 1904.

PUBLISHED WEEKLY AT 1321 WALNUT STREET PHILADELPHIA BY THE AMERICAN-MEDICINE PUBLISHING COMPANY

VOL. VII, No. 8.

FEBRUARY 20, 1904.

\$5.00 YEARLY.

The immigration problem of the United States is intelligently discussed from a number of standpoints in a recent number of *Charities*. Careful calculations have been made of the cost of caring for the poor of New York State, the amount being placed at \$24,000,000 a year. As the foreign born are over half, the cost of their maintenance is at least \$12,000,000 a year in one State only. The alien insane of the whole country will cost something like \$50,000,000 a year within the next ten years. The 1901 report of the United Hebrew Charities of New York says that, "A condition of chronic poverty is developing in the Jewish community of New York that is appalling in its immensity. Forty-five percent of our applicants, representing between 20,000 and 25,000 human beings, have been in the United States over five years; have been given the opportunities for economic and industrial improvement which this country affords, yet notwithstanding have not managed to reach a position of economic independence." Dr. Shively has estimated that 23,000 tuberculous immigrants were landed in New York in 1902. Every teaching of medicine, of patriotism, and of sound common sense dictates the more rigid and thoroughgoing exclusion of the undesirable immigrant. We are deteriorating as regards the national health and degrading the future of our country in all ways by the wretched folly of freely admitting the diseased and the paupers of foreign countries.

The Colorado Medical Legislative League is an organization which should find imitators in most of our States. Not deterred by the recent failure to secure the desirable legislation demanded as regards the practice of medicine in the State, the public spirited physicians have united to carry on the struggle until success shall be gained. "The purpose of this league," says the constitution, "shall be to form a nonsectarian body through which the united medical profession of the State of Colorado may succeed in improving and in enforcing the medical statutes. The league will confront every legislator and candidate for office, including aspirants to the gubernatorial chair, with the proposition of support or antagonism, as the case may be, if they favor or oppose its objects." This will make the influence of the profession felt politically. Further, the league desires to carry on a campaign of education, that the many erroneous ideas

promulgated by the press may be corrected and the purposes of genuine professionalism shown in their true light. The organization will work in harmony with the previously active National Auxiliary Congressional and Legislative Committee for Colorado, the peculiar conditions making the two bodies a necessity in the State. The quacks of every kind of fraud and every degree of ignorance will always be united, and the powerful influence upon State legislators which they can always rally must be offset by similar unity on the part of the intelligent who know the price which the community must pay in money, health, and life, where charlatanism abounds.

Greed and the Establishment of Tuberculous Camps.—According to report the State Charities Aid Association of Pennsylvania charges that the bill recently adopted by the Legislature regulating the establishment of camps for the tuberculous was made so restrictive as to location by the influence of rich men that practically such camps are almost prohibited except in cities. The bill is declared to be one of the most disastrous measures which has ever received legislative and executive sanction. Those who favored the law, says the association, showed an unwarranted fear of the effect of establishing camps of the sort contemplated on the health of the neighborhoods in which they are located, and the law as it stands may prevent thousands of sufferers from tuberculosis in the State from receiving the care and treatment which would result in their improvement. We have previously alluded to the prejudice of many in the community as to the establishment of hospitals in their neighborhood, when the truth is that the hospitals, of course, exercise the most beneficial, instead of a baneful effect upon the health conditions of their vicinity. One can hardly believe that the men owning tracts of land in the highland and forest regions of Pennsylvania are both so stupid and so malevolent as the above report implies. Any one of them may be either so dull-witted or so egregiously selfish, but a combination of the two characteristics is too great an affliction for a large number of persons, even if riches be added. If the report is true, the voters and physicians of Pennsylvania have it in their power, and should speedily execute their will, that such legislation and such legislators should receive a sharp command of *about face!*

Oysters Preserved by Boric Acid.—The New Hampshire State Board of Health continues to show what noble work State boards may do when they are both scientific and imbued with the proper spirit of protecting the health of the people. Those interested in the pure food question and the adulteration of foods should read the January number of the *New Hampshire Sanitary Bulletin*. Among other reforms, we notice its crusade against the use of boric acid in oysters and clams. Seventy-seven samples of oysters were examined for boric acid, and in 34 cases it was present. When the inspection was first commenced every sample of tub oysters contained boric acid, and the results obtained from samples from Dover, Portsmouth, Manchester, and Concord showed conclusively that it was the practice of Boston wholesalers to add boric acid, or a preparation known as "preservaline," and containing boric acid, to every tub of oysters that they sent out. A vigorous correspondence with dealers in Norfolk and Providence River tub oysters produced such beneficial results that on the last inspection of oysters from the above-named cities but little boric acid was found. The practice of preserving oysters by the liberal use of boric acid permitted the small grocer or marketman to keep oysters on his counter, without ice, in warm weather, as long as any remained unsold. Undoubtedly a preservative active enough to arrest decay in such perishable articles as oysters, under such conditions, would not fail to arrest, in a like manner, the action of the digestive ferments. Clams are equally liable to adulteration by preservatives, and because of their less common use may contain even larger quantities of boric acid. The action of the wholesale houses in quickly abandoning the use of boric acid when notified by their customers that they were not allowed to sell goods so treated, proves the practice to be unnecessary.

Gardens of Medicinal Plants.—In connection with a recent editorial on the conservation of medicinal plants we wish to call attention to a very practical suggestion by Dr. Albert Schneider, of the California College of Pharmacy.¹ After pointing out the value of botanic gardens, in an historic review of the subject, he outlines briefly a plan for the establishment of gardens of medicinal plants in the United States. Regarding the possible criticism that this plan is premature, the statement is made that partially successful and abortive efforts have been made to establish such gardens and that plans for the establishment of several others on a large scale are now maturing. While the writer believes that the United States should possess several large gardens of medicinal plants he strongly emphasizes the unprofitableness of duplicate work. It therefore is desirable that these gardens should be supplemental to each other, each to investigate and develop the resources of its surrounding territory and of certain definite foreign lands. The following gardens are already begun or contemplated: New York Botanic Gardens (ready for active work); Shaw Botanic Gardens, St. Louis (in operation); Philadelphia (contemplated); Ann Arbor Garden (in operation); Indiana

State University (contemplated); San Francisco Garden (active work begun). The suggestion offered, and one that we hope to see adopted, is that the movers in the establishment of these and any other contemplated gardens meet in the near future, mature their plans, and determine upon a division of labor. Such gardens, which would serve for the instruction of students and the public, develop the possibilities of the country for raising medicinal plants, and in time add millions of dollars to the resources of the United States, should be laid out only on the broadest lines. Hence the necessity for cooperation that the work may be properly begun.

One Overlooked Factor in the Increase of Insanity.—The new element in modern civilization which is not recognized, and which is known to be a profound source of many derangements is school life and reading. Suddenly, the compulsory or chosen occupation of reading and near use of the eyes in a thousand occupations has been the dominant element in the life of the city dweller. Printing, books, schools, libraries, cheap books, newspapers, and handicraft occupations have appeared, and compel a physiologic or unphysiologic activity which, whether harmful or not, is a new function, and one to which in evolution, neither the mind nor the body has been habited, and especially to which the highest, most delicate, and most used sense organ has never been bred. Moreover, this sense organ is demonstrably imperfect in a large proportion of all persons, and the action of the malformed eye, as has been demonstrated by science, and by thousands of clinical cases, begets disease of eye, of cerebral action, of feelings, and of nutrition. Malfunction is the beginning of all disease, and of many it is the middle and end. Suicide, it has been found, is exactly in proportion to the number of hours of school life and study demanded in the country concerned. To this suggestive fact is now added the demonstration that insanity is almost precisely in the same proportion. When, lastly, it is observed that the use of the eye demanded by the civilization of the last century or two is one that its evolution has never provided for, either in structure or physiology, one gets a glimpse of morbid mental action in the making. When it is found that the insane and criminal have an astonishingly high proportion of high optical defects, the suggestion grows to conviction that the morbid action of the eye and its resultant cerebral functions are considerable causes of the increase of insanity.

Suicide of a Convicted Financier.—Probably no more dramatic incident can be found recorded in the whole dark page of the annals of crime than the termination of the life of the late financier, Whitaker Wright, which occurred in the London Law Court some days ago. But, most astounding of all is, perhaps, the consummate coolness with which he comported himself during the last scene, while knowing that his mortal existence was limited to a few minutes. The fact of his maintaining a quiet conversation with his legal adviser during this interval, and falling back in his chair to enter on the death struggle, while engaged in the act of

¹ American Journal of Pharmacy, January, 1904.

"lighting his second cigar," is one which cannot, we believe, be paralleled in the whole dark history of self-destruction. And the perfect finish of every detail of his preparation is still further illustrated in the fact that he must have had "the very best advice" in the choice of a poison. The deadly compound, potassium cyanid, to the use of which the suicide is attributed, causes destruction of life by the same mysterious power over the vital functions which is possessed by prussic (hydrocyanic) acid, the most rapid in action of all known toxic agents. A molecule—the smallest particle of a chemic compound which displays the characteristic properties thereof—consists, in the case of each of those compounds—of three atoms. That of potassium cyanid is represented by KCN; that of prussic acid by HCN. The difference lies in one atom only, and that one harmless. Chemistry defines an acid to be: "A compound containing hydrogen replaceable by a metal." The H of prussic acid is replaced, in the formation of potassium cyanid, by the element (K) potassium. And this atom of K is in turn easily displaced by (H) hydrogen, when exposed to the action of an acid. The latter agent is always present in the normal contents of the stomach. Accordingly, the change of potassium cyanid into prussic acid is always effected after swallowing. But, as a rule, this change is gradual, as the quantity of acid present in the stomach is usually small. On this account there is generally an interval—up to 15 minutes or 20 minutes, or so—before the consequent symptoms begin. When a fatal dose of prussic acid has been taken, the symptoms, in typical cases, commence instantaneously; the patient at once falls in a state of complete insensibility, and passes into a state of violent tetanic convulsions. Life has been known to become completely extinct in so short a period as two minutes. But the (usually) gradual decomposition of potassium cyanid in the stomach, and its consequent gradual absorption, leaves a well-marked interval before the onset of the symptoms. For a similar reason, the onset is likely to be very much less violent; the tetanic convulsions may be completely absent. Consideration of these various facts strongly indicate the unsurpassable skill with which the poison used by Wright had been chosen. No other lethal agent known to science could have given so dramatic an effect. The result of taking prussic acid would have been a ghastly termination of life. Most of the other potent poisons would have left a possibility of antidotal treatment; and many of the most destructive offer but a terribly painful means of ending life. The skill with which the convicted man availed himself of this means of escape was remarkable. Nobody saw him take the poison, and he was under continuous supervision. It is surmised that he swallowed the poison when passing his handkerchief across his face, immediately after the sentence was passed.

Fatal Mistake of Potassium Cyanid for Ammonium Carbonate.—There is another physical feature of potassium cyanid which is of very great importance in connection with its poisonous properties. This is a resemblance in appearance of its crystals to fresh ones of ammonium carbonate. This crude resemblance has

caused loss of human life. Of course, the odor of ammonium carbonate would form a sufficiently distinctive criterion to most observers; there is also the fact that crystals of ammonium carbonate soon become covered with a white powder—from the facility with which the superficial molecules give off their water of crystallization—which does not occur to those of potassium cyanid. But the fact remains that the mistake has occurred with the worst effects. The ammonium salt is very frequently prescribed in conjunction with syrup of wild cherry as a stimulating expectorant—especially in the bronchitis of old people. Such a prescription was issued from a Dublin office about a third of a century ago, and the mistaken substitution of potassium cyanid was followed by a fatal result.

"Ref. D.," is the degree conferred by an M.D. and LL.D., upon graduates of his college, and he promises that every \$9.00 invested with him will realize at least \$100. To prove it he publishes glowing testimonials that the business of the Ref. D.'s (Doctors of Refraction) is netting his graduates \$15, \$20, \$25, and even \$30 a day—"better," as one of them says, "than a \$5 a day position." A personal letter from the Doctor of Laws to one of our subscribers reads:

As a number of druggists, physicians, dentists, and jewelers have expressed a desire to have a short course on the eye, and also the theoretical part of optics and applied part of refraction taught them, we have decided to give a postgraduate course in refraction, for one month, to all of this class for \$25. Certificate with name engrossed therein would cost \$2.

This course will be given one month, beginning the first of January and continuing for four months, thus giving all students a week at a time at the college, with the privilege of returning home and reading for three weeks of each month and returning one week of each month to the college. This one time is the only opportunity you will have, as we have plenty of room in our hall so we can accommodate two hundred and fifty students which we hope to have. Should you decide to take one month here straight through it will be all O. K. with us.

The medical profession is particularly instructed that "a diploma from this school admits you to any State in the Union without taking any more examinations." The diseases and abnormalities of the eye, according to permitted popular custom do not concern medicine, or the practice of medicine. In legislation the eye is not a part of the body. If not ethical and scientific, the M.D., LL.D. faculty, board of trustees, and college, is at least religious, although he has not D.D. attached to his name. He heads his circular with a fairly pertinent and suggestive quotation from the Bible: "Ye shall know them by their fruits. He that reapeth receiveth wages, and gathereth fruit unto life that both he that soweth and he that receiveth may rejoice together."

Therapeutic Stones.—The sacred, magical and curative properties of certain stones—large and small—appear to have ranked among the items of the *Pseudodoxia epidemica*, among all races and nations, and throughout all recorded ages. The colossal monolith and the small "graven image" of stones are wellknown examples of the first of these properties. Among the prominent specimens of the second, may be noted the items of popular medieval belief, that a *diamond* placed

under the pillow would notify the conjugal infidelity of a wife; that an *emerald* would break if worn during sexual intercourse; that the wearing of a *sapphire* was a preservative against all enchantments; that the fume of an *agate* would effectually avert the approach of a tempest; that the wearing of a *chrysoprase* would "make one out of love with gold;" and that the carrying about of an *amethyst* surely preserved the owner from being "overtaken" by drunkenness—an item of belief to which the etymology of its name is due. To a kindred form of credulity must be ascribed the wondrous properties which were ascribed to *China dishes*, when first imported to Europe from the Celestial empire. It was confidently said of these "by Scaliger and others;" "that they admit no poyson, that they strike fire, that they will grow hot no higher than the liquor in them ariseth." With regard to the curative powers of various stones, we may seasonably quote the remark of the celebrated author of the "Religio Medici:" "He must have more heads than Janus, that makes out half of those vertues ascribed unto stones, and their not onely medicall, but Magicall proprieties, which are to be found in Authors of great name. In Psellus, Serapion, Evax, Albertus, Aleazar Marbodeus; in Maiolus, Rueus, Myllus, and many other." And the same author goes on to state some of his own opinions in this connection: "That Lapis Lazuli hath in it a purgative faculty we know, that Bezoar is Antidotall, Lapis Judaicus Diureticall, Corall, Antiepilepticall, we will not deny, that Cornelians, Jaspis, Heliotropes, and bloud-stones, may be of vertue to those intentions they are impled; experience and visible effects will make us doubt." And just now the fact of the persistence of such forms of belief is forcibly brought home to us by the announcement—in a diurnal (lay) contemporary—of the unquestioning faith which is placed in the efficacy of "mad-stones" by a large proportion of our own fellow-citizens. There are even now many of those precious talismans in this country; and "the believers in their efficacy always know where the nearest one is kept." One of them had long been the property of an Ohio negro, and was placed after the death of its owner in the State Library at Columbus. There it was recently applied to the wound caused by the bite of a supposedly rabid dog. The dog recovered, and the woman to whom it was applied died of blood-poisoning caused by the unclean contact. We are also informed that such a stone was kept in the Virginia State Penitentiary for years, and was open to all comers for application to the bite of a mad dog, or other allied wound. One such (perhaps the same) was at a later date sold by auction for \$39. Still more famous was that brought from Russia in 1887 by a physician of that country who settled in Nevada. It had previously been exploited in that country for at least a century and a half—a fact supported by documentary evidence. The document was written in native Russian; and as nobody concerned could read it, everybody implicitly believed what they were told of it. The owner offered the stone for sale at \$1,500, and a joint stock company was formed for the purchase. A thousand shareholders advanced \$1 each; and the balance was made up by a farmer who became

its keeper when the purchase was completed. Its fame still flourishes and it is said that an offer of \$3,000 has been refused for it. Such is faith—in our own land of progressive enlightenment! Can we be surprised that eddyism, antivivisectionism, antispectacleism, and all other such isms, still continue to flourish—in so fertile a soil?

BOOK REVIEWS

A Practical Handbook of the Pathology of the Skin: An Introduction to the Histology, Pathology, and Bacteriology of the Skin, with Special Reference to Technic.—By J. M. H. MACLEOD, M.A., M.D., M.R.C.P. Philadelphia: P. Blakiston's Son & Co., 1903.

The first 7 chapters of this handbook are devoted to a consideration of various fixation, embedding, and staining processes, and to the special microscopic technic found most useful in the study of the morbid anatomy of the skin. In subsequent chapters the general pathology of the skin is considered, the various lesions characteristic of cutaneous disease are described as they occur in the epidermis, the corium, and the several appendages of the skin, such as the hair, nails, sebaceous and sweat glands, etc. The special diseases of the skin are not considered, except as they serve to illustrate the occurrence of the lesions described. A brief account of the normal histology of the several divisions of the skin precedes in each instance the description of the alterations produced in them by disease. A chapter is devoted to an account of the blood changes occurring in certain diseases of the skin, and to the special methods used in their demonstration and study. The concluding chapters of the manual are concerned with the various pathogenic micro-organisms found on and in the skin, and the various staining and culture methods employed in their demonstration. Many excellent illustrations are scattered throughout the book, which serve to make the text still clearer. We have only words of praise for this handbook, which should be found upon the work-table of every student engaged in the serious study of diseases of the skin. In it are to be found all the modern methods employed in the microscopic study of the pathology of the skin, as well as clear and concise descriptions of the tissue alterations characteristic of cutaneous disease. The demand for, and the appearance of, such books is a striking indication of the real scientific spirit with which diseases of the skin are being studied at the present time.

The American Year-book of Medicine and Surgery for 1904.—Edited by GEORGE M. GOULD, A.M., M.D. In 2 volumes. W. B. Saunders & Co., Philadelphia, New York, London, 1904.

The American Year-book of Medicine and Surgery continues to maintain its high place among works of its class. Indeed, the issue of 1904, if anything, is even better than the excellent issues of the previous years. The distinguished corps of collaborators which the editor has enlisted as his assistants is sufficient guarantee that the essential points of progress are brought out, and the collaborators' notes and commentations are excellent. In the illustrative feature the 1904 issue fully maintains its reputation, there being 14 full-page insert plates, beside a number of excellent text-cuts. The volumes are as nearly authoritative as possible, constituting a necessary part of each physician's library.

Progressive Medicine. A Quarterly Digest of Advances, Discoveries, and Improvements in the Medical and Surgical Sciences.—Edited by HOBART AMORY HARE, M.D., assisted by H. R. M. Landis, M.D. Vol. iv, December, 1903. Lea Brothers & Co., Philadelphia and New York.

Volume iv, the concluding volume of 1903 of Progressive Medicine, comprises a critical review of the recent literature on diseases of the digestive tract and allied organs, the liver, pancreas, and peritoneum, by Dr. John C. Hemmeyer; on anesthetics, fractures, dislocations, amputations, surgery of the extremities, and orthopedics, by Dr. Joseph C. Bloodgood; on genitourinary diseases, by Dr. William T. Belfield; on diseases

of the kidneys, by Dr. John Rose Bradford, F.R.C.P.; on physiology, by Dr. Albert P. Brubaker; on hygiene, by Dr. Charles Harrington; and a practical therapeutic referendum, by Dr. H. R. M. Landis. The reviews of the literature are excellent—little if anything of importance having escaped the observation of the different departmental editors, who themselves add to the value of the reviews by their critical comments. Together the 4 yearly volumes afford a valuable and comprehensive review of the progress of medicine.

Transactions of the American Surgical Association. Volume xxi.—Edited by RICHARD H. HARTE, M.D. For sale by William J. Dornan, Philadelphia.

This comprises a volume of more than 700 pages, which includes all the papers, together with the discussions, presented at the meeting of the American Surgical Association in Washington, D. C., May, 1903. This, of course, warrants for it much information on nearly all the prominent surgical subjects before the profession today.

Modern Microscopy.—By M. I. CROSS and MARTIN J. COLE. Third edition, revised and enlarged. Chicago: W. T. Keener & Co., 1903.

The third edition of this work contains 285 pages and 76 illustrations. It is divided into 3 parts: 1. The microscope and instructions for its use. 2. Microscopic objects; how prepared and mounted. 3. Microtomes: their choice and use. The book is still intended for beginners and students and can be recommended as a valuable aid. It furnishes very many points of detail that cannot be found in larger and more pretentious works upon the subject. At the same time many of the directions are necessarily short, this being particularly true of the preparation and use of stains. Parts I and III are the most satisfactory.

Transactions of the Association of American Physicians.—Eighteenth session held at Washington, D. C., May 12-14, 1903. Volume xviii. Philadelphia, 1903.

The appearance of the transactions of this Association is always looked forward to as being largely the record of medical advancement in this country during the preceding year. The present volume is no exception to the rule. It contains 46 papers, being a book of 709 pages. Mention of the articles worthy of attention would be practically giving a list of contents. Many of them have already been published in current journals. Among the most important are: Studies on Certain Phases of Bovine Tuberculosis, by Kober and Smith; Chronic Cyanosis, by Osler; Phases of Anemia and Leukemia, by Morse, Blumer and Gordinier, Kelly, Dock and Warthin; Studies on the Action of Alcohol, by Hare and Cabot; Anatomic Studies of Cases of Hereditary Ataxia, by Barker.

A Compend of Pathology, General and Special. A Students' Manual in one Volume.—By A. E. THAYER, M.D. Second edition. Philadelphia: P. Blakiston's Son & Co. 1903.

This volume is a combination, with revision, of the 2 compends issued by the author in 1902. A chapter on the Nervous System and several illustrations have been added. The work in its present form contains nearly 700 pages, and is attractively bound in limp cloth. While this compend, as all books of its type, must be of greatest value to the students of the author, it will undoubtedly prove of assistance to other students and to practising physicians who have not the time for consulting more pretentious works upon the subject.

Diseases of the Horse.—Special report of U. S. Department of Agriculture, Bureau of Animal Industry. By Drs. PEARSON, MICHENER, LAW, HARBAGH, TRUMBOWER, LIAUTARD, HOLCOMBE, HUIDEKOPER, STILES, and ADAMS. Revised edition. Washington: Government Printing Office, 1903.

This book of 600 pages is the revised edition of the Special Report, issued in 1890. The greater number of the chapters have been revised by their original authors. A new chapter on "Examination of a Horse" by Dr. Pearson, has been added. As much as possible of the text has been freed from technical terms in order that horse owners generally may make practical use of the work. To them it must prove of great value. The Chief of the Bureau, Dr. D. E. Salmon, under whose super-

vision the book was revised, states that the present edition is issued for distribution principally by senators, representatives and delegates in Congress, the Department having no copies for general distribution.

Manual of Medicine.—By THOMAS KIRKPATRICK MONRO, M.D. W. B. Saunders & Co. Philadelphia, New York, and London, 1903.

The author of this manual states in his preface that the book is intended primarily for students, but it is hoped that it may also be of service to junior physicians. This hope should be realized, as the work is one of the best manuals of medicine that we have seen. Many points are omitted, as must be expected, but in the 877 pages is condensed a vast amount of information. The most valuable feature of the work is that what is given is put in such plain, easily-read style that the student can understand it, and thus appropriate it to his own use. The subject matter is thoroughly up to the date of publication, but in these days of progress a work on medicine lacks some things, even on the day it comes from the press.

BOOKS RECEIVED.

[Prompt acknowledgment of books received will be made in this column, and from time to time critical reviews will be made of those of interest to our readers.]

Third Biennial Report of the Board of Control of State Institutions of Iowa: For the Biennial Period ending June 30, 1903.—Bernard Murphy, State Printing, Des Moines, 1903.

Social Diseases and Marriage.—By PRINCE A. MORROW, A.M., M.D., Emeritus Professor of Genitourinary Diseases in the University and Bellevue Hospital Medical College; Surgeon to the City Hospital; Consulting Dermatologist to St. Vincent's Hospital, etc., New York. In one octavo volume of 390 pages. Cloth, \$3.00, net. Lea Brothers & Co., Publishers. New York and Philadelphia, 1904.

Prostatic Hypertrophy from every Surgical Standpoint.—By GEORGE M. PHILLIPS, M.D., and 40 distinguished authorities. Edited and compiled by S. C. MARTIN, JR., M.D. Lewis S. Matthews & Co., St. Louis, Mo. Price, \$1.75.

The Neurological Practice of Medicine: A Cursory Course of Selected Lectures in Neurology, Neurology, Psychiatry and Psychiatry. Applicable to General Practice. With 177 illustrations. Designed for students and general practitioners of medicine and surgery.—By CHARLES H. HUGHES, M.D., President of the Faculty and Professor of Neurology, Psychiatry and Electrotherapy, Barnes Medical College. Former Major and Surgeon-in-Chief of Schofield, Winter, Hickory Street and McDowell's College Military Hospitals, Superintendent Missouri State Insane Hospital, etc., 1903.

The Blues: (Splanchnic Neurasthenia); Causes and Cure.—By ALBERT ABRAMS, A.M., M.D. (Heidelberg), F.R.M.S., Consulting Physician, Denver National Hospital for Consumptives, The Mount Zion and the French Hospitals, San Francisco; President of the Emanuel Sisterhood Polyclinic; formerly Professor of Pathology and Director of the Medical Clinic, Cooper Medical College, San Francisco. Cloth, 240 pages, illustrated, postpaid, \$1.50. E. B. Treat & Co., Publishers, New York.

The Self-Cure of Consumption without Medicine: With a Chapter on the Prevention of Consumption and other Diseases.—By CHAS. H. STANLEY DAVIS, M.D., Ph.D., Member of the Connecticut Valley State Medical Society; Physician to the Curtis Home for Old Ladies and Children, etc. E. B. Treat & Co., New York City, 1904. Price, 75 cents.

How to be Successful as a Physician: Heart to Heart Talks of a Successful Physician with his Brother Practitioners. The Church Publishing Company, Meriden, Conn., 1902.

A Textbook of Legal Medicine and Toxicology.—Edited by FREDERIC PETERSON, M.D., Chief of Clinic, Nervous Department of the College of Physicians and Surgeons, New York; and WALTER S. HAINES, M.D., Professor of Chemistry, Pharmacy, and Toxicology, Rush Medical College, in affiliation with the University of Chicago. Two imperial octavo volumes of about 750 pages each, fully illustrated. Philadelphia, New York, London: W. B. Saunders & Co., 1903. Per volume: Cloth, \$5.00 net; sheep or half morocco, \$6.00 net.

A Manual of Operative Surgery.—By SIR FREDERIC TREVES, F.R.C.S. New second edition, revised by the author and JONATHAN HUTCHINSON, JR., F.R.C.S. In two octavo volumes. Volume I containing 750 pages and 245 illustrations. Volume II, 824 pages, 228 illustrations. Per volume, half morocco, \$6.50 net. Lea Brothers & Co., Publishers, Philadelphia, New York.

Diseases of the Eye.—By L. WEBSTER FOX, A.M., M.D., Professor of Ophthalmology in the Medico-Chirurgical College of Philadelphia; Ophthalmic Surgeon in the Medico-Chirurgical Hospital. With 5 colored plates and 296 illustrations in the text. D. Appleton & Co., New York, London, 1904.

Army Inefficiency: Its Greatest Cause.—By A. C. PROFFIT, M.B. J. & A. Churchill, London, 1903. American selling agents, P. Blakiston's Son & Co., Philadelphia.

A Short Practice of Gynecology.—By HENRY JELLET, B.A., M.D., B.Ch., B.A.O. (Dublin University), F.R.C.P.I., L.M., Ex-Assistant Master, Rotunda Hospital, Extern Examiner in Midwifery and Gynecology, Royal University of Ireland, etc. Second edition, revised and enlarged, with 223 illustrations. J. & A. Churchill, London, 1903. Price, \$3.75.

The Sympathetic Nerve: From Original Dissections: Life Size.—By BYRON ROBINSON, M.D., Chicago, Ill. E. H. Colegrove, Chicago, Ill. Price, 50 cents.

Acute Poisoning: A Chart giving Descriptive Classification and Varieties with Special Symptoms, Chemic and Physiologic Antidotes, Fatal Dose, Simple Tests and Remarks on Treatment.—Victor Koechl & Co., New York City.

AMERICAN NEWS AND NOTES.

GENERAL.

Examination for Pharmacologists.—The United States Civil Service Commission announces an examination on March 1, 1904, to secure eligibles from which to make certification to fill a vacancy in the position of pharmacologist (male) in the Bureau of Plant Industry, Department of Agriculture, at \$1,800 per annum, and other similar vacancies as they may occur. Applicants will not be assembled for this examination. Persons who desire to compete should at once apply to the United States Civil Service Commission, Washington, D. C., for application form 1312, which should be properly executed and filed with the Commission at Washington, with the material required, prior to the hour of closing business on March 1, 1904.

The AngloAmerican Medical Association of Berlin desires to inform the profession of its organization and purposes. Realizing the difficulties which beset the path of the stranger, the Association places its services at the disposal of physicians who intend to study in Berlin. They are cordially invited to attend the meetings which are held weekly, and any information concerning the work to be had here will be gladly given to any member of the profession who will communicate, on his arrival in Berlin, with Dr. J. H. Honan, president, Latzow Strasse 78, or with any of the undersigned committee.

ALBERT J. MAYER, M.D., Secretary,
DAVID SHANNON, M.B.,
WM. W. GRAVES, M.D.

Examinations for Army Medical Service.—The examination of applicants for appointment as assistant surgeon in the United States Army will be resumed in Washington immediately after the close of the present session of the Army Medical School; it will embrace the full examination (as heretofore), at the conclusion of which those found qualified will be commissioned. Full information as to the requisite qualifications for appearance for examination, method of application, nature and scope of examination, etc., may be obtained upon application to the Surgeon-General, U. S. Army, Washington, D. C. The examining board will probably reassemble about the middle of April next, and those desiring to present themselves before the board should make application at once. Applicants are restricted in age to 30 years, and a year's hospital experience or its equivalent in private practice is required.

Bequests to Charity.—PHILADELPHIA: By the will of Henry C. Cochrane, who died December 18, 1902, a sum aggregating nearly \$100,000, was left to numerous hospitals, homes for the aged and other charity institutions in Philadelphia. The largest recipient was the Pennsylvania Hospital, which received \$10,000. The remainder of the sum was divided in smaller amounts among various institutions. By the will of Hannah W. Gadsen more than \$20,000 is distributed among 25 charities in the city of Philadelphia, the Episcopal Hospital, which received \$5,000, being the largest recipient. NEW YORK: By the will of Mary C. Seguin the sum of \$10,000 was left to the Sheltering Arms of New York; \$10,000 to the Society for the Relief of the Destitute Blind; \$10,000 to the Home for Old Men and Aged Couples. By the will of Mrs. E. W. Aldrich, \$80,000 is left to various charity institutions. Among the hospitals which are recipients of various sums are St. Luke's Hospital, Home for the Incurables, New York Protestant City Mission Society, etc.

Miscellaneous.—DR. WILLIAM OSLER, professor of medicine at the Johns Hopkins University, will give this year the Ingersoll lecture at Harvard University, his subject being "Science and Immortality."—THE PRIZE OF THE SWEDISH MEDICAL ASSOCIATION has been awarded to Professor M. G. Blix, of Stockholm, for his work on the temperature of the muscles.—MR. HENRY PHIPPS has given \$20,000 to the Johns Hopkins Hospital to establish a clinic for tuberculous patients. THE TENTH QUADRENNIAL CONGRESS OF THE POLISH PHYSICIANS AND SCIENTISTS will be held this year in Lemberg, Austria, July 20 to 24. Professor E. Machek is the chairman of the committee of arrangements, and Professor W. Sieradzki is secretary. Dr. Francis E. Fronczak, of Buffalo, N. Y., is the representative of the committee for the United States.—THE UNION PROTESTANT INFIRMARY OF BALTIMORE: One of the heaviest losers in the conflagration was the Union Protestant Infirmary, and it has been stated that the institution would be required to close its entire new building, and limit the scope of its work to 15 beds. The hospital is one of the best known in the city. It was almost entirely supported by charitable contributions and bequests, and the entire new building and porches were built in this manner. It is understood that practically all of its funds and endowments were in warehouses in the devastated territory, and that the insurance will not begin to cover its losses.—MEDICO-CHIRURGICAL HOSPITAL, PHILADELPHIA: One year ago an explosion occurred in the Medico-Chirurgical Hospital, which damaged the structure to a considerable extent. The State Legislature appropriated \$20,000 to aid

in reconstructing the building. This has now been completed, and a number of new improvements have been added.—THE AMERICAN JOURNAL OF NURSING contains, among other valuable reading matter, an account of the Pennsylvania State meeting. This was the second meeting of the Pennsylvania Nurses' Association, and was held in Harrisburg, January 20 and 21, the president being Miss Anna E. Brobson. A paper was presented by Miss Sarah A. Rudden, entitled "The A B C of Registration." Rebecca Halsey, of the Jewish Hospital, Philadelphia, was the author of a paper entitled "A Plea for Organization"; this was read by Miss Greaney, of the Woman's Hospital. Reference was made by Miss Milne, of the Presbyterian Hospital of Philadelphia, to the preliminary education for nurses, a course which is being given at the Drexel Institute, Philadelphia. A reception was given to the nurses by the members of the Academy of Medicine, at which more than 200 guests were present.—THE JOHNS HOPKINS NURSES ALUMNÆ MAGAZINE: The number published in December, 1903, appears in a neat and attractive form, containing much valuable reading matter, particularly for nurses. A brief editorial review of what has been accomplished in the work of this journal and its supporters.—THE MEDICAL RECORDER is the title of a monthly journal, the first number of which appeared in January, 1904. The editor is Dr. Oscar Dowling; the associate editors are Dr. Louis Abramson and Dr. R. H. T. Mann. The journal is published at Shreveport, La. The first number contains a number of valuable papers and suggestions.—JOHNS HOPKINS' LOSS: The Baltimore Sun says: One of the results of the Baltimore disaster has been the serious crippling of the work of the Johns Hopkins Hospital, whose income was largely derived from the rent of buildings which it owned in the burned district. Sixty-eight warehouses, widely scattered, belonging to the hospital, have been destroyed, and the hospital has lost the income from them for possibly 2 years. The hospital property destroyed aggregates nearly \$1,300,000. Owing to the complete destruction of the general office of the hospital, on Holliday street, it is impossible to estimate how much insurance may be recovered. The money derived from the rental of these buildings, which is estimated at \$100,000 a year, was devoted to the free work of the hospital, with about \$35,000 derived from the rental of other property in control of the trustees.

EASTERN STATES.

New Hampshire Licensed Embalmers' Association.—The fourth annual convention of the New Hampshire Licensed Embalmers' Association, held this month in Concord, was very successful, and exceedingly profitable to all who attended. We believe it to be the duty of every licensed embalmer in the State to join this organization. Methods and practices in connection with the disposal of the dead have been so advanced in recent years that the demands upon the embalmer and undertaker are much greater than formerly. The better preservation of the dead, methods of protecting the public in cases of infectious and contagious diseases, transportation of corpses, the legal requirements of other States in the preparation of bodies shipped to them, and many other questions make it necessary for the embalmer to be well-informed upon these points. The only States in the union that have not yet established rules and regulations to govern the transportation of the dead are Arkansas, California, Maryland, Massachusetts, Mississippi, New Jersey, Nevada, Oregon, Rhode Island, and the District of Columbia. New Hampshire was the first of the New England States to establish such regulations. The result is, that bodies cannot now be transported unless they are properly prepared, and, furthermore, it is now possible to ship bodies dead of certain contagious and infectious diseases that prior to the adoption of the regulations was not permitted. The advantages of the law have been demonstrated in many ways.—[New Hampshire Sanitary Bulletin.]

NEW YORK.

Typhoid in Watertown.—Information from Watertown, under date of February 11, says: Typhoid fever is prevalent in this city. Local health officials state that there are between 150 and 200 cases, and the 2 public hospitals are crowded. The State Health Commissioner has appointed Professor Olin H. Landsteth, of Union College, as sanitary expert to investigate the cause of the epidemic and take charge of the situation.

Pneumonia and Architecture.—The Bulletin of the Chicago Health Department, for the week ended January 30, says: "Pneumonia is a disease of modern architecture—of the custom, steadily growing during the past 15 or 20 years, of covering every available square foot of land with the building and using every available square inch within its walls for little cubby-holes and cubicles in which human beings are to work and live and sleep. Air famine is the most potent cause of pneumonia, as it is of tuberculosis. The high priest of modern hygiene, Edmund Parkes, more than a generation ago, formulated a table demonstrating that 3,000 cubic feet of air per hour is necessary for healthy life indoors, and during the latter third of the generation our architects have been steadily getting farther and farther away from this standard, and the pneumonia incidence and mortality have been as steadily increasing."

Trade Unions to Fight Tuberculosis in New York City.—It is planned that the fight against tuberculosis shall be taken up by the various trade unions, and committees have been appointed accordingly. The *Weekly Bulletin of the Clothing Trades*, in its January issue, says: "A systematic inspection will be inaugurated with the aid of the business agents of the different local unions so as to ascertain the sanitary condition of the shops and cause the observance of precautions that would tend to eliminate the disease so largely prevalent in the congested districts where the making of clothing is centralized. It is proposed to interest the operatives in the subject and enlist their cooperation. Rules, in the different languages, are to be posted in all the shops for their guidance, and circulars and pamphlets are to be distributed so as to acquaint the workers with the nature and gravity of the disease and the necessity for following the instructions of the best authorities. In this way it is hoped to effectively cope, so far as the industry is concerned, with the dread scourge that has so sorely afflicted mankind."

Important Legal Decision.—The gist of a case carried before Justice White, of the Supreme Court of the United States, is this: A New York firm sold to a Baltimore firm goods, which, on delivery, were found to be adulterated; they were not accepted and litigation arose, the contention being made by the New York firm that the goods were not adulterated, at least within the meaning of the New York statute. Justice White emphatically sustains this view, allowing a wide latitude to the several States for the exercise of their police power in the enactment of sanitary laws. The court says in part: "We are of opinion that it is within the power of a State to exclude from its markets any compound manufactured in another State which has been artificially colored or adulterated so as to cause it to look like an article of food in general use, and the sale of which may, by reason of such coloration and adulteration, cheat the general public into purchasing that which they may not intend to buy. The Constitution of the United States does not secure to any one the privilege of defrauding the public."

PHILADELPHIA, PENNSYLVANIA, ETC.

Testimonial in Recognition of Gift.—The College of Physicians of Philadelphia decided, without a dissenting voice, to express their thanks to Andrew Carnegie for his magnificent donation of \$50,000 to that institution. The acknowledgment will be in the form of an engraved certificate enclosed in a gold frame and sent to the donor.

Cases of Tuberculosis to be Registered.—The Public Health Department of the city of Philadelphia has inaugurated an extension in its fight against tuberculosis. The plan calls for the registration of every case of tuberculosis, giving the name, color, age, and address of the person affected so soon as the diagnosis of the case is made. The establishment of this system will, physicians say, be a great aid in combating the spread of tuberculosis. With the knowledge of every case of the disease in the city, the authorities can take intelligent means to prevent infection. The spreading of the disease is said to be largely due to the fact that the tuberculosis germs are conveyed from the tuberculous to other persons who live with them or move into houses where they have lived. Under the new system it will be possible to follow every case, take proper sanitary measures and disinfect houses where the tuberculous have lived before any one else is allowed to move there.

SOUTHERN STATES.

Instituting War on Yellow Fever.—Information from Laredo, Texas, under date of February 2, says: "A party of distinguished physicians left Laredo for Mexico to confer with members of the Board of Health there in an effort to devise means to prevent a recurrence of a yellow fever epidemic such as visited northern Mexico and the southwest border of the United States last year."

WESTERN STATES.

Mortality of Michigan During January, 1904.—There were 3,126 deaths reported to the Secretary of State for the month of January, corresponding to a deathrate of 14.7 per 1,000 population. The number was 184 larger than that registered for the preceding month, and is also greater than the number for January, 1903. By ages there were 490 deaths of infants under 1 year of age, 210 deaths of children aged 1 to 4 years, and 982 deaths of elderly persons over 65 years of age. The age distribution was practically the same as for the preceding month. Important causes of death were as follows: Pulmonary tuberculosis, 176; other forms of tuberculosis, 25; typhoid fever, 57; diphtheria and croup, 83; scarlet fever, 34; measles, 12; whoopingcough, 19; pneumonia, 412; influenza, 101; cancer, 134; accidents and violence, 180. There was 1 death from smallpox, which occurred in Kalkaska county.

Distress during the Year 1903.—The *Chicago Tribune* says: "The loss of life by disasters in 1903 has been large. Shipwrecks on the ocean and inland lakes and rivers have taken 1,935 lives. Over 4,000 persons have been killed and over 5,000 injured in railroad accidents. These figures include only

the severely injured, and the list of killed is mainly passengers. The complete returns, including those killed and injured on electric roads, will be much larger, as *The Tribune's* record includes only prominent disasters. There have been numerous other disasters involving heavy loss of life. Cyclones and rock-slides in April killed 127 persons. By cyclones and the floods at Topeka and Kansas City in May 286 persons perished. In June there was a series of unusual disasters. Eighty lives were lost by a cyclone at Gainesville, Ga.; 58 by a flood at Spartansburg, S. C.; 31 by a cloudburst at Clifton, Ariz.; and 200 by a cloudburst at Heppner, Ore. Then the country enjoyed immunity from great disasters until December 30, when between 500 and 600 lives were lost by the burning of the Iroquois Theater—the crowning horror of the year's record at home or abroad. The embezzlers and defaulters in 1903 got away with \$6,586,165, not a large sum as compared with the average of the last 50 years."

FOREIGN NEWS AND NOTES

GENERAL.

Decrease of Tuberculosis in Germany.—Official figures show that in German cities of 15,000 or more inhabitants tuberculosis has been steadily decreasing in fatality; the number per 10,000 in the 5 years ending in 1881 was 357.7; in 1886, 346.2; in 1891, 304.5; in 1896, 255.5, and in the 5 years ending 1901, 218.7.

How Long Has This Been Going On?—An exchange says editorially: The London *Daily News* has constantly mocked at the perils of "dumping," alleging with much reason that it was an advantage to buy the things you need as cheaply as possible. Examination of a recent bill of entry, however, has shaken this faith, for interpolated in a long list of drugs and nostrums appeared "£800, Common Sense Exterminator." Whether this lethal import be "made in Germany," or whether it bespeaks the malice of the subsidized American patent medicine industry, has not yet appeared, but the matter, in any case, demands the earnest attention of Mr. Chamberlain's fiscal commission. The *Daily News* finds in this item an explanation of the general abeyance of common sense in the kingdom, and asks pathetically, "How long has this been going on?"

A Heroine Martyr.—Dr. John F. Jackson, F.R.G.S., having recently visited India, says: "When I reached India I learned that there were 500,000 lepers in that country, who lead a life of absolute loneliness, and who are considered unclean outcasts. Their religion puts them under a curse, and of all people they are the most needy and most helpless. I visited 30 colonies of lepers, and in many instances found the people in them living in huts unfit for habitation, neglected and uncared for. I visited Miss Mary Reed, the American missionary, who is doing such heroic work among the lepers. Her experience is painfully unique from the fact that she is the only living missionary who has become a leper. She contracted the disease while engaged in ordinary mission work and resolved to devote her life to her fellow sufferers. She has been working devotedly for 12 years. I found her presiding over a fine institution, which she herself founded, in a remote corner of the Himalayas."

Women Medical Inspectors Appointed in England.—The Battersea Council, says an English exchange, has appointed a woman inspector, who is charged with instructing young mothers in their duties toward their children. What she has to do is put down as follows: To visit houses where births have occurred, and to instruct the mothers in the preparation of infants' food and the proper method of infant feeding. To keep under constant supervision houses occupied by dirty tenants. To endeavor to raise the standard of cleanliness. To visit certain houses where there are cases of nonnotifiable disease, such as whoopingcough, and to advise as to the nursing and care of the patient. To visit houses where there are dirty and neglected children. To visit houses where infantile deaths have occurred. To assist, as far as possible, in house-to-house inspection. Women who have undertaken similar works in Liverpool and other English cities have been found extremely useful persons.

OBITUARIES.

John M. Adler, at his home in Philadelphia, February 11, aged 76. He graduated from the Princeton University in 1844 and from the medical department of Columbia University, Washington, in 1847; one time surgeon to the Panama railroad during its construction. During the Civil war he was in charge of the military hospital in Davenport, Ind. Some years later he settled in Philadelphia, becoming a member of various medical societies and a Fellow of the College of Physicians. He was for several years consulting physician to Girard College and chief medical examiner in Pennsylvania for the Mutual Life Insurance Co., of New York. He was recognized as an authority in literature, especially in the period represented by the writings of Samuel Johnson.

E. A. deSchweinitz, at his home in Washington, D. C., of uremia, February 15. He was a graduate of the University of North Carolina in 1882; received the degree of Ph.D. from the University of Göttingen, Germany, in 1886; and graduated in medicine from the medical department of Columbian University, Washington, D. C., 1894. He was dean of the National Medical College, Medical Department of Columbian University, Washington, D. C.; professor of toxicology in the same and director of the biochemical laboratory of the Agricultural Department, Washington, D. C. He was one of the best known chemists in the United States. He was a Founder of *American Medicine*.

Jacob Repelye Ludlow, at his home in Easton, Pa., February 10, of pneumonia and a complication of allments, aged 80; a graduate of the medical department of University of Pennsylvania in 1845 before he was 21 years of age. He served as surgeon in the Union Army during the Civil war both on the field and hospital service. He was a member of the Loyal Legion and prominent in Masonic circles. He retired from active service five years ago.

Howard J. Seeley, of Brooklyn, February 7, at Asheville, N. C.; a graduate of the Long Island Medical College in 1898. He was appointed professor of histology for the summer course in his alma mater and assistant surgeon to the Williamsburg Hospital. His health failing he was obliged to take up his residence at Asheville, where he died.

Edwin Barnes, at his home in Pleasant Plains, N. Y., January 22, aged 59; a graduate of the Albany (N. Y.) Medical College, in 1865, one time president of the Dutchess County Medical Society, vice-president of the New York Medical Association, and at the time of his death was physician of Vassar Hospital at Poughkeepsie.

August H. Trow, at his home in Ethan, S. D., aged 81; a graduate of the Medical School at Castleton, Vt., in 1862. He formerly practised at Maysville, N. Y., and later at Chatfield, Minn., having lived at Ethan, S. D., 2½ years. He was a member of the Minnesota House of Representatives in 1859, 1860, and 1872.

John Herbert Sangster, of heart disease, at his home in Toronto, January 27, aged 72; a graduate of the University of Toronto, in 1864. He was a prominent figure in the social and professional life of Toronto, and in 1894 was elected a member of the Ontario Medical Council.

James W. Garden, at his home in Sandy Hook, January 26, aged 41; a graduate of the New York University, in 1889; a member of the Bridgeport (Conn.) Medical Society, Fairfield Medical Society, and Connecticut Medical Society.

Charles E. Mammeré, at Oconomowoc, Wis., February 8; a graduate of Cornell University in 1880, and of Rush Medical College some years later. He was one time lecturer on surgery at the Chicago Polyclinic Hospital.

Henry Scott Vernon, at his home in Rushford, Minn., February 1, from pneumonia; a graduate of Rush Medical College in 1900; a health officer of Lewiston, Minn., and member of the American Medical Association.

August Krehbiel, at his home in New York, February 11, aged 65. He was graduated in medicine in Germany and settled in New York in 1864. He was a member of the consulting board of the German Hospital.

David Krausgill, of pernicious anemia, at his home in Chester-town, Ind., January 23, aged 56; a graduate of the Medical College of Ohio, Cincinnati, in 1879; a member of the American Medical Association.

Charles A. Wheeler, at the Massachusetts General Hospital, February 11, aged 68. During the war he was commissioned an assistant surgeon in the Fifteenth Massachusetts Regiment, and served until 1862.

Joseph E. VanCamp, of apoplexy, while driving to see a patient at Carlisle, Pa., February 11, aged 66; a graduate of the University of Michigan in 1870 and a veteran of the Civil war.

Joseph G. Rooney, at St. Mary's Hospital, Hoboken, February 4, from gangrene, aged 37; a graduate of the medical department of the New York University in 1891.

Charles W. Dodd, at his home in Chicago, February 8. He was a prominent physician and local Swedenborgian leader. The cause of his death was apoplexy.

Henry Benson Phillips, of Benson, La., at a sanitarium in Shreveport, La., February 3, of pneumonia, aged 35; a graduate of Vanderbilt University in 1893.

Robert Hanna, of Greenock, was killed in a railroad accident near Guffey station, January 20, aged 32; a graduate of Jefferson Medical College, Philadelphia.

John Hannahan, of heart disease, at his home in Elwood, Ind., January 25, aged 45; a graduate of the Kentucky School of Medicine, Louisville, in 1893.

Thomas F. Cawley, at his home in Saylorsburg, Pa., January 28, aged 47. He was a graduate of the Bellevue Medical College in 1880.

William H. Henning, at his home in Jeffersonville, Va., January 23, aged 74; a graduate of the Jefferson Medical College in 1853.

Edward Thomas, aged 75, and formerly of New Berne, N. C., died suddenly in a cigar store in New York, February 3.

CLINICAL NOTES AND CORRESPONDENCE

[Communications are invited for this Department. The Editor is not responsible for the views advanced by any contributor.]

TREATMENT OF DIPHTHERIA IN CHILDREN.

BY

EDMUND DEWITT, M.D.,
of Lawrenceville, N. J.

To the Editor of American Medicine:—I wish to present in succinct form some of the conclusions I have arrived at concerning the treatment of diphtheria, deduced during a period of experimentation with remedies since 1878. The germ of diphtheria had not been discovered at that date. Not until Klebs, in 1883, and Loeffler, in 1884, discovered the bacillus, did we have the firm ground of fact to stand upon. Learned, acute, and experienced investigators were endeavoring to ascertain the germ cause of several contagious diseases, and diphtheria was one that especially attracted their attention.

So much had been claimed in this field of investigation, that many physicians concluded that the cause of diphtheria was of germ origin, and began the use of such remedies in its treatment, as were deemed to possess germicidal ability. Unfortunately, many of us concluded that all old remedies were to be laid aside and new ones discovered. The good old trusty weapons that had carried us through many a fight were to be discarded, and something new and untried take their places. As a consequence the mortality was appalling. The manufacturing pharmacist, always on the alert, soon produced remedies galore! I found the new measures of attack of so little value that I trembled for the safety of my patient when called to a case of diphtheria. In 1883 I began the use of chlorin and of mercury, in various combinations. I found chlorin in most combinations, too irritating for continued use in treatment. Mercuric chlorid was too powerful a remedy to be left with careless nurses. Tincture of muriate of iron was a remedy I could push to extreme dosage if necessary, and the mild mercurous chlorid was just as efficient while it was safer than mercuric chlorid. I found quinin prevented, to some extent, the constitutional effect of mercury on the system, and enabled me to push the mercurial treatment. Hence I always gave it in doses sufficient to produce cinchonism. To an adult I gave two .13 gm. (2 gr.) pills of sulfate of quinin every 4 hours.

Calomel 1 mg. (½ gr.), triturated with .13 gm. (2 gr.) of pulverized saccharin dropped on the tongue, without liquid, every half hour. Tincture of muriate of iron, 30 drops, in water every 2 hours.

Small pieces of ice taken into the mouth frequently.

For children I prescribe proportionally larger doses than for adults. I use the same dose of calomel in children as in adults. In malignant cases in children I give the mercurial preparation every quarter hour.

I have used these remedies since 1878, in some 150 cases of diphtheria, and have never had injurious constitutional effect from the use of the mercurial preparation. I am not afraid of gastric irritation being produced by the iron chlorid. However if it occurs I reduce doses and it soon subsides without any bad sequel.

The result of the foregoing treatment is as follows: In from 24 to 36 hours the temperature is inside of 1° above normal and the pulse corresponds to the temperature. The germ cause is destroyed. From 6 to 10 hours after treatment is begun, no live germs can be found in the throat and there is no danger of contracting the disease from the exhaled breath. Of course inflammation is still present and the membrane to be detached and come away, after the cause of the disease is wiped out.

The only experience I have had in the employment of anti-toxin is as follows:

The patient, a girl of 6, had a malignant case of diphtheria. The mother had a number of boarders for whom the child was neglected, and the medicines were not regularly given. On my second visit I found the child asleep in a cold room, lying on the zinc under the stove-pipe. The child's voice indicated extension of the disease into the larynx. I had her sent immediately to St. Francis Hospital at Trenton. She was

operated upon and sent home 2 weeks after recovery. Just 9 days after she returned home, her little brother became sick with the disease. He was sent to the hospital for treatment, and was returned home 2 weeks after convalescing. The father was very fond of the child, and nursed and caressed him. Just 9 days after this child's return the father was taken sick with diphtheria. Both patients had been treated at the hospital by antitoxin. Unquestionably the little boy contracted the disease from his sister's breath, and likewise the father from the son's. One of the sisters in the hospital told me that both of the children had been bathed and the clothing had been disinfected and washed, and that there could have been no possibility of contagion from the clothing or from the skin.

I am convinced that in the foregoing cases, the disease was contracted from the children's breath. I believe no one claims that antitoxin destroys the diphtheria germs. But it is claimed that it so changes the toxins produced by the germs as to make them innocuous. Why not take the bull by the horns and destroy the germs and prevent the formation of toxins in the system? To proceed to destroy the influence of the toxins upon the system is taking the bull by the tail, and one would expect results consistent with such a procedure.

This immediate vicinity is somewhat subject to diphtheria, and a year does not pass without some cases. Yet I have not had a death from diphtheria in over 20 years, some 150 cases. Can many claim such a record?

THE EARLY DIAGNOSIS OF TUBERCULOSIS.¹

BY

JOHN J. GILBRIDE, M.D.,
of Philadelphia.

Assistant Demonstrator of Anatomy at the Medico-Chirurgical College; Clinical Assistant, Diseases of the Stomach and Intestines, Philadelphia Polyclinic, etc.

It is not many years since most physicians were little concerned as to the early or late diagnosis of tuberculosis, or in what stage of the disease a patient might be, for all cases were considered hopeless. Even under favorable circumstances, when the patient had sufficient means to enable him to suspend all occupation, seek a change of climate, and be free from mental care, life might be prolonged for only a short time.

However, with the discovery of the tubercle bacillus by Dr. Koch a new era opened, and since that time the progress made has been remarkable and most gratifying. When a diagnosis of tuberculosis was made without some of the more valuable and indispensable instruments of precision, and the patient recovered, we came to the conclusion that we were wrong in the diagnosis. However, a greater familiarity with the postmortem table has given ample proof of the correctness of our original diagnosis. The percentage of cases at autopsy in which healed lesions of tuberculosis are found, and in which the patients died from some other disease than tuberculosis, ranges by various observers from 5% to 50%. Several years ago a French physician stated that 72% of the bodies autopsied at the morgue showed lesions of healed tuberculosis.

Even Hippocrates held that the anemic with loss of appetite and the presence of cough should go to the mountains, live in the open air, on a diet of milk, etc. Experiments, by dieting patients suffering from tuberculosis were being conducted in the wards of some of the local hospitals about 8 years ago, and the idea was ridiculed, but this was only another step in the proper direction.

We are now getting better proof of the curability of the disease by the number of recoveries recorded. The statistics of the various sanatoriums show conclusively that if the disease is recognized in its incipency the prospect for cure in most cases, and arrest in others, is very bright; but this cannot be applied to those patients who with but few exceptions have passed the first stage of the disease, although there are patients in the third stage, with a cavity present, the walls of which are healing, and in whom the physical condition is fair, with slow pulse, and little or no fever, who have a better chance for recovery than many with consolidation in whom a breakdown of the lung tissue has not begun, and whose feeble vitality is not sufficient to tide over the process of softening.

¹ Read before the Northern Medical Society of Philadelphia, September 25, 1903.

The Loomis Sanatorium gives a report of 99 patients treated in 1899:

	Admitted.	Discharged.
Incipient cases without bacilli.....	12	25
Incipient cases with bacilli.....	23	10
Moderately advanced.....	50	45
Far advanced.....	14	14
	99	94

Another report from the same institution of 456 patients treated, with 42 remaining at the time of the report.

INCIPIENT CASES (163).

Discharged cured.....	61
Disease arrested.....	25
Improved.....	59
Unimproved.....	1
Died.....	1

Total.....147

MODERATELY ADVANCED (216).

Discharged cured.....	7
Disease arrested.....	10
Improved.....	121
Stationary.....	11
Unimproved.....	33
Died.....	3

Total.....185

FAR ADVANCED (17).

Improved.....	3
Stationary.....	3
Unimproved.....	60
Died.....	9

Total.....75

This gives 58% of the incipient cases cured, or disease arrested, 9% of the moderately advanced cured or arrested, and only 4% of the far advanced were benefited.

It appears that a higher percentage of females than males are afflicted with the disease. However, of the cures, 60% were in females, as compared with 40% in males. The reason given for this is that females are more regular in their habits and take better care of themselves.

Some writers believe that the menstrual period exerts an unfavorable influence, but there are no statistics to substantiate this belief. It is common for female patients to attribute their illness to the cessation of menstruation, while the actual cause is tuberculosis.

Squires¹ reports the case of a girl of 14, who had high fever, consolidation, bacilli, etc., and he calls attention to the fact that she had never menstruated and believed that this circumstance had much to do with her recovery; and further that in cases in which the development of pulmonary tuberculosis coincides with the establishment of menstruation the prognosis, as a rule, is bad; that is, when the tubercle appears about the age of puberty. Therefore the prognosis in any given case is much influenced by the consideration whether definite evidences of puberty have or have not appeared.

The most favorable age for recovery appears to be from 18 to 30 years; after that time, while the chances for recovery are less, still the disease does not progress so rapidly and the tissue seems to offer a greater resistance. Other factors which militate against recovery from this disease are that many patients do not seek the advice of a physician until the disease is well advanced; the long time necessary for cure; and the lack of discipline on the part of the patient. If he or she does not improve right away, all treatment is stopped.

Tuberculosis attacks the lungs as part of a general infection; it may even simulate an acute pneumonia, or a more common form, and the one most frequently met is of slow and insidious onset, the form which is at times so difficult and of such great importance to diagnose early.

From a pathologic standpoint the progress of the disease as seen in the lungs is divided into 3 stages: First, infiltration in which the tubercle is the predominant factor. The tubercle is a nonvascular body, composed of connective tissue cells, endothelial cells from the blood vessels, and leukocytes. There may be present giant cells. These latter are considered cells that have made an abortive attempt at proliferation. Infiltration does not, as a rule, show a great tendency to break down, because the tubercle still receives a blood supply from the surrounding lung tissue which has not yet become involved. Second stage: Consolidation in which

there is coalescence of the tubercles with solidification of the lung; a subsequent softening with cheesy or caseous degeneration from deficient blood supply. This produces the third stage or cavity formation. However, it is not uncommon to have the presence of all three of these pathologic conditions at the same time throughout the lung, each giving rise to certain signs and symptoms. The most common sites for the invasion of the lung are the apices, the lower lobes posteriorly, upper part of middle lobe of right lung and the thin portion of left lung that overlies the heart, but, of course, there is not any of the lung exempt.

The upper border of the middle lobe of the right lung is often diseased, and may be easily overlooked. I found this to be affected only after careful examination recently in 3 instances. This is best exposed and most satisfactorily examined by having the patient sit with the back toward you; the clothing should be removed from chest, and the patient place the hands on top of the head; this elevates and draws the scapulas forward, exposing the desired area.

It should also be remembered in examining the apices that these parts extend upward from 1 in. to 1½ in. above the clavicle, and do not extend further outward than the inner half of clavicle. Some textbooks would lead one to believe that the lung extended to the acromial end of the clavicle; also, the right lung does not extend downward as far as the left posteriorly, due to the position occupied by the liver.

Patients frequently consult their physicians because they become tired easily, have impaired digestion, loss of strength and of ambition. I remember one patient who did not lose a pound in weight, while the sputum was literally filled with tubercle bacilli. There may be a slight chilliness at times, which should be thoroughly investigated, especially where malaria abounds.

There may be sudden hemorrhage, but the symptoms mentioned are those generally most complained of. Cough is present, but expectoration at this time may be absent; anemia may be slight or marked. Some writers say there is a pretuberculous stage. The pulse² in the pretuberculous stage is not influenced by change of position, and is of feeble tension. Tachycardia³ is characterized by the greatest instability with a low blood-pressure. Bozzolo also mentions a condition of the gums, red in the early stage, blue in the advanced, and white in the scrofulous, as a diagnostic feature. I should think these signs subject to a great deal of error. Dilation of pupil either unilateral or bilateral, by involvement of the meninges, or the iris, is mentioned. Family history is of importance. Many patients complain of pain anteriorly over the entrance of the bronchus, becoming aggravated by fatigue. At this time what condition do we find when the disease has not passed infiltration of the lung? Inspection is negative, palpation may reveal slightly increased vocal fremitus, which the patient himself sometimes detects; percussion is negative, or there may be a slight impaired note. On auscultation a few moist rales may be heard, or can be brought out by having the patient take deep inspirations or cough, especially in the morning on arising. I found this in one case when at any other time of the day it was not discernible. If rales are present they frequently make their appearance earliest in the interscapular region, over the entrance of the bronchi into lung.

The right bronchus enters the lung at about the fifth dorsal vertebra and the left enters opposite the sixth dorsal vertebra, passing downward and outward, while the right enters at more of an acute angle. "Cog wheel," or jerky breathing, is an almost positive sign; also, expiration may be a little prolonged and roughened or tubular in quality. Sputum has probably not made its appearance, unless the lung condition has been preceded by a tuberculous laryngitis. There may be restriction of the diaphragm. Some time ago increased temperature was considered infallible, but at present does not play so important a part, especially in the early stage, for as high as 40% are afebrile. To detect any elevation of the temperature, the thermometer should be used every 2 hours and registration made. If elevation does exist, it may not exceed 99° or 100° F., and this is most commonly found about 4 p.m. Osler⁴ says examinations must be made daily, and sometimes it will be only after the twenty-fifth or thirtieth time that the exact seat

of the complaint can be located. The anemia, according to 60 cases by Cabot, is not caused by the tubercle bacilli, but by *Diplococcus lanceolatus*, which is associated with the tubercle bacilli; if diarrhea is present, it has a tendency to drain the body of albuminoids and produce severe chloranemia.

The lung signs become more marked as the disease advances, and are ordinarily accompanied by loss of weight and the presence of sputum. Percussion reveals impaired resonance or dulness; auscultation, moist rales and bronchial breathing.

If the sputum examination fails to reveal the presence of tubercle bacilli, repeated attempts should be made, for many times it is only after numerous efforts that they have been found. The number of bacilli in any given specimen does not appear to be of much importance, although if the case is watched and improvement continues, there will be a gradual diminution in the number. It is further believed that the bacilli are capable of multiplying in the secretion, thus explaining the presence of a greater number in the morning sputum than at other times. The tubercle bacillus is liable to be mistaken for the bacillus of leprosy, bacillus of syphilis and the smegma bacillus, but these can be differentiated by their staining properties. In examining urine for tubercle bacilli, the urine should be drawn through a catheter, and thus the possibility eliminated of the presence of the smegma bacilli.

The value of tuberculin as an aid in diagnosing tuberculosis appears to be a little doubtful at present. However, something of that character is what we want, something that will enable us to make an accurate diagnosis before many of the other signs appear, and it is too late to save many of our patients. The tuberculin test proves reliable in most cases, says E. C. Trudeau,⁵ but 30% are latent tuberculosis, and do not give any signs or symptoms. Patients may react to tuberculin, says Dr. J. D. Madison,⁶ and no evidence be found of tuberculosis at autopsy. He also reported 6 cases of completely healed tuberculosis which gave a reaction, while others of proved tuberculosis did not react to the maximum dose. Otis reports 60 cases of syphilis in which the tuberculin test was tried, and all gave a reaction. Bender⁷ reports 37 cases tested with tuberculin; all except two reacted, and these two were the most advanced. He also says that the serum reaction is greatest in the early cases.

The röntgen ray is undoubtedly a valuable adjunct for making an early diagnosis, but the requisite apparatus is possessed by so few physicians that it does not play a great part, and it is the general practitioner to whom we must look for an early recognition of the disease, for he sees the vast majority of cases. The signs and symptoms are not very pronounced in the early stages of the disease, for if they are of the classified type the case is no longer in the early stage, the disease is far advanced, and cure uncertain. Allbutt,⁸ giving the statistics of Turban, says of the patients received in the first stage, 84.4% were cured or permanently relieved. Therefore, if cases are seen and recognized early there is the greatest prospect of cure.

ANOMALOUS CONDITION OF THE KIDNEYS.

BY

CHARLES S. CAVERLY, A.B., M.D.,

of Rutland, Vt.

President of Vermont State Board of Health; Professor of Hygiene, Medical Department, U. V. M.

A boy of 16, a prisoner in a State penal institution in this city got into a "scrap" with a fellow prisoner, and after some half dozen blows had been exchanged, he suddenly straightened up, fell backward, and, gasping 3 or 4 minutes, died. It could not be learned that he received any blows except in the face.

At the instance of the State's attorney, I made an autopsy the following day to determine the cause of death. This autopsy revealed an anomalous condition of the kidneys which seems worthy of record.

The left kidney was apparently wanting and there was no

suprarenal capsule. The right was found in its normal position; when attempting to remove it, the upper end was found attached to a mass which led toward the left of the body. Following this mass, another body, somewhat kidney-shaped, was located, firmly bound down to the spinal column at the level of the lower lumbar vertebrae and covered by a dense mass of connective tissue, in which were the abdominal vessels. This proved to be a somewhat small kidney. It was attached in a

A careful inquiry into the personal and family history of this boy revealed nothing extraordinary, except that he had a violent temper and was an inveterate cigaret smoker. There is an older brother and sister living and in health. He was committed to this institution for larceny. He had previously served a term at the Reform School.

The pathologic examination of these kidneys, the photograph of the whole mass and the microphotograph were made

Section of the two kidneys.

solid mass to its fellow of the right side, and was somewhat obliquely placed across the spinal column, its lower end pointing to the left. The double organ had, as it lay in the body, the appearance sometimes described as "horseshoe," but the union of the 2 organs was at their upper extremities.

The photograph, which is made from a vertical and longitudinal section of the double organ, does not show this "horseshoe" shape, but gives an accurate idea of the extent of the

by Drs. Wiltse and Stone, of the Vermont State Laboratory. The following condition was shown: Macroscopically, the two organs are firmly adherent. On section no line of demarcation, but a perfect continuity of tissue between the two. The cortical zones of the two organs are fused into a common cortex at the point of union. This common cortex is no wider than that of the individual organs and their noncontiguous surfaces. From this common zone, tubules pass each way, forming pyramids which terminate in papillae in their respective pelves.

No macroscopic connection between these pelves is demonstrable. The pelvis of the smaller organ is rudimentary and that of the other small and irregular. The markings of both sections are very irregular, being almost obliterated in large areas. The capsule strips easily. Each organ seems to have its own blood supply, but there is a free anastomosis of the smaller vessels in the common cortex.

Microscopically, the right (large) organ shows many areas of small round-cell infiltration, cloudy swelling, and almost complete degeneration of the tubular epithelium, showing a condition of diffuse nephritis. The left (smaller) organ shows the same condition, perhaps slightly less marked. Both organs show small areas of nearly normal tissue.

The microphotograph shows a condition that was common to both kidneys.

Microphotograph of section of cortex.

fusion of the 2 organs. The right kidney had a normal suprarenal capsule, but none was found corresponding to the left.

The right ureter was normal, opening normally into the bladder. The left ureter was somewhat rudimentary and was occluded at its entrance into the bladder. The bladder was normal in size, location, and capacity. The prostate was normal.

The boy had a mitral heart disease. The pathologic examination showed a chronic diffuse nephritis, and this condition with the heart disease was given as the cause of death.

A THIGH TRUSS FOR FEMORAL HERNIA.

BY

WILLIAM H. BENNETT, M.D.,
of Philadelphia.

Every physician must have experienced the unsatisfactoriness of the spring truss as ordinarily used for the relief of femoral hernia.

Few patients will wear one any length of time, and those who do, probably receive but little benefit therefrom.

Such use of the spring truss is unscientific, and if it had not been successfully used first for inguinal hernia, no one would have devised such an appliance for the relief of femoral hernia. The action of a spring truss partially encircling the abdomen with its end resting on the thigh, is that of a spring on a door. With every lessening of the angle between the thigh and abdomen, as in walking and sitting, there must be either a greatly increased pressure at the thigh end of the spring, or a slipping

of the end out of its original position. Both generally take place.

In a case of left femoral hernia in a woman lately under my care, I failed entirely to adjust a spring truss in the way ordinarily attempted. I therefore employed a small truss encircling the thigh only. After four months' use it has proved so satisfactory that I desire to suggest the device to others, that its value may be thoroughly tested.

In this case it has been thus far efficient, comfortable, and without drawbacks. The device is so simple that it seems probable that some one else may have made use of it, and though I have not been able to learn that such is the case, I write this article rather to bring an apparently useful appliance to the notice of the profession, than to claim originality for it.

In my case the thigh measured at its upper part, 20 inches in circumference, and I used an ordinary hard-rubber spring truss, marked "20," such as is sold for infants. The combined length of its strap and spring, exclusive of its pad, was 20 inches. The spring was a half-inch broad. The pad belonging to such a truss is a little too small, and it is desirable to substitute for it, the pad of the truss next larger in size. In my case I employed a water pad, which is more comfortable and more easily kept in position.

There are two possible ways of applying such a truss. The spring may be placed in front of the thigh with the pad pointing downward, as the pad would be applied to an inguinal hernia, or by inverting the truss, the spring can be placed on the back of the thigh and the pad will then point upward.

I believe the latter is much the better way. It is at least more satisfactory to the patient in that the spring is less likely to be seen through the clothing, lying as it does, just below the gluteal fold.

In a woman it is entirely concealed.

Much of the success of such a truss depends upon careful adjustment. The strength of the spring must be just right. The truss must be held in place largely by the grip of the spring on the thigh, rather than by the pinch of the pad. The spring must be of a length to extend just far enough around the thigh to give that grip, but not far enough to make the outer end of it extend beyond the outer edge of the thigh when it is straightened out by pressure in the sitting position. The pad must fit snugly. It must point in exactly the right direction, and its plane must correspond with the plane of the portion of the thigh on which it rests. The strap should be loose when standing, and just taut when sitting. It must never constrict the thigh.

I believe in some cases a loose piece of elastic webbing would be better than the strap, but in mine the strap was entirely satisfactory, and it is certainly more durable. To prevent the possibility of the truss slipping down, it should be supported at each end of the spring by strips of elastic webbing attached to a belt or girdle worn around the waist. This webbing should be just tight in the upright position. In a woman the webbing can be comfortably attached to her ordinary girdle. I need not say that it is important to see that the large vessels are not compressed by the pad. This is true of any truss.

The only inconvenience complained of by my patient was that at first the spring would occasionally give the back of the thigh a pinch on sitting down. She learned to overcome this.

DEATH UNDER NITROUS OXID ANESTHESIA.

BY

WINFIELD S. PUGH, JR., M.D.,

of Washington, D. C.

Assistant Surgeon, United States Navy; Formerly House Surgeon, King's County Hospital, Brooklyn, N. Y.

Of all the anesthetics in use by surgeons of the present day there is none in which the mortality is so small (claimed by many to be almost nil) as it is under the influence of nitrous oxid gas. I have had a most extensive experience with this drug, using it in such major cases as double mastoid disease complicated with pneumonia, amputations of the thigh, strangulated umbilical hernia, shoulder-joint operations, etc., and in

cases of lowered vitality I am very partial to its use. In looking over the literature upon the subject I find that very few deaths under its influence are recorded, and so the following case may be of interest:

While in charge of the surgical wards of Dr. A. T. Bristow at King's County Hospital, New York, a burly negro was admitted who complained of slight pain in the left forearm. History as follows: J. S., aged 33, single; occupation, longshoreman. Previous personal and family history, negative; does not use alcohol or tobacco.

General appearance, large well-nourished man, of about 185 pounds in weight; 5 feet, 11 inches tall.

Present trouble was first noticed about a week ago, when a small splinter lodged beneath the nail of the index finger; the wound bled a little, but apparently healed without any further annoyance, until 3 days later, when he noticed that the flexor surface of the left forearm was becoming quite painful and swollen, and that flexion caused considerable pain over area and extending down to fingers.

Examination on admission revealed a small area of cellulitis, on the flexor surface of the forearm, midway between the elbow and wrist, with beginning suppuration. Physical examination of chest revealed heart and lungs apparently normal.

Urinary examination presented no abnormalities; blood-examination, considerable leukocytosis. On the following morning the patient was taken to the operating-room, anesthetized with nitrous oxid gas, and an incision made over the area in the left arm, and a small amount of pus evacuated. This procedure, including time of production of anesthesia did not last over 1½ minutes, when the patient suddenly ceased to breathe, the pulse continuing to beat fairly rapidly. Artificial respiration was at once begun, anus dilated, hypodermics of strychnin, ether, amyl nitrate, and aromatic ammonia given, followed by 1 pt. hot saline infusion in median basilic vein, without avail. It is interesting to note that the pulse-beat continued perhaps 30 seconds after respiratory movement had ceased.

Postmortem examination revealed slight visceral engorgement, a very small vegetation on one of the pulmonary leaflets of heart, and marked cerebral anemia; all other organs were apparently normal.

I am reporting this case not to condemn this means of anesthesia, for on the contrary I value it most highly, but as a caution that death may occur under its influence as well as under the more powerful drugs, chloroform, ether, ethyl bromid, etc.

THE MISFORTUNE OF A COLLEAGUE.

To the Editor of *American Medicine*.—In reading "The Misfortune of a Colleague" in the last issue, I wish to add a few words.

I have known Dr. Remick for many years, and have been a neighboring practitioner, 4 miles distant, for 4 years. All that the brother says of him is true; no more conscientious, self-sacrificing man labors in this world than he, and his great loss has been a crushing blow, but he is of the stuff that knows not defeat, and is making his long, tiresome rounds, doing all the good he may, the same as ever. I trust that the profession will assist—a little from those that can afford, in the way of books and instruments especially, together with a word or two of cheer, will be everything toward strengthening our brother's heart.

I would make a correction in Dr. Remick's address; it is Tamworth, N. H., instead of Farnworth.

Very truly yours,

LESTER W. LORD, M.D.,

West Ossipee, N. H., February 9, 1904.

[Beside the contributions acknowledged we have received and forwarded to Dr. Remick's address a second box of medical books, and a check for \$10.00 from subscribers to *American Medicine*. Other contributions have also been sent direct to Dr. Torrey.—Ed. *American Medicine*.]

Improvement in the Streets and Sewerage System to be Inaugurated in the Rebuilding of Baltimore.—It is stated on reliable authority that in the rebuilding of the devastated area of Baltimore, that the streets will be widened, and a new sewerage system instituted. To Dr. William Osler, of Johns Hopkins Hospital, will be intrusted largely the planning of this renovation. It is stated that instead of narrow, dark, foul, disease-breeding alleys, and small low-ceiled stuffy houses in certain quarters there will come wide-paved streets, and houses to which air and sunlight will be admitted. Baltimore is to be congratulated in securing the services of one so eminent in sanitary matters as is Professor Osler. It is a relief to know that at least some good, will come out of the fearful conflagration.

ORIGINAL ARTICLES

THE LIFE CYCLE OF AMOEBA COLI IN THE HUMAN BODY: A PRELIMINARY NOTE.*

BY

CHARLES F. CRAIG, M.D.,
of San Francisco, Cal.,

First Lieutenant and Assistant Surgeon, U.S. Army; Pathologist and Bacteriologist to the U. S. Army General Hospital, Presidio of San Francisco, Cal.

The life cycle of *Amoeba coli* within the human body has always been the subject of much research, but until recently little definite has been known about it. This is especially true of the manner of reproduction of this organism. Until quite recently it has been supposed that the reproduction of *Amoeba coli* occurred by simple division, although some authorities, as Grassi and Doflein¹ have described cysts containing multiple nuclei, and have regarded these as indicating segmentation. Opie,² in writing upon *Amoeba coli*, states that the exact method of reproduction has not been demonstrated, but that it is probable that simple binary division occurs, although evidence favoring this is wanting.

In a previous contribution,³ published in 1901, I described certain appearances in amoebæ, which I stated were in all probability spores. In this article, speaking of the unstained organisms, I said:

It is possible that some of the so-called vacuoles are in reality spores, the mother parasite eventually rupturing and setting them free. Reasoning from what occurs in other similar organisms, this seems the most probable method of reproduction.

In describing preparations stained with methylene-blue and fuchsin, I stated:

These fullgrown amoebæ show from 1 to 3 or more large vacuoles which are entirely unstained, but beside these there are numerous small, oval or round, very dimly stained areas scattered throughout the protoplasm, which are evidently not vacuoles, and correspond to the same areas observed in the very young forms. The vacuoles and the dimly stained areas are entirely distinct, the dimly stained areas being oval, or round, and much smaller than the vacuoles, having a dim outline, and evidently not penetrating the organisms as do the vacuoles.

In the conclusion of this article I stated:

There occur in all but the degenerate forms of amoebæ, similar round or oval unstained areas, uniform in appearance, and most numerous in the large fullgrown forms, being entirely absent in the vacuolated shells of amoebæ. These areas resemble similar areas observed in stained segmenting malarial plasmodia which are in them, due to the young spores. Reasoning from analogy, it may be that these areas in the amoebæ are also spores.

As regards the reproduction of amoebæ, Clarke⁴ and other authorities give two methods, one by simple transverse division, and the other by spore formation. The latter method of reproduction, however, was not, at the time these authorities wrote, proved for *Amoeba coli*. Since writing the article referred to, a very important contribution to this subject has been made by Schaudin,⁵ in which he gives his conclusions, arrived at after 8 years of study, as to the manner of reproduction of amoebæ and his observations regarding *Amoeba coli* confirm the opinions I expressed in my original article.

Schaudin studied the amoebæ occurring in the healthy intestine and those occurring in dysentery, and believes that the two are entirely distinct varieties. To the former he has given the name *Entamoeba coli* and to the amoeba of dysentery the name of *Entamoeba histolytica*.†

* Published with permission of the Surgeon-General, U. S. Army.

† The "law of priority" governs the name of any new species discovered throughout the civilized world. Thus, if an organism is classed as an amoeba by the original investigator and it is not afterward proved that it belongs to some other genus, this name stands. This is also true of the specific name. While amoebæ were discovered in the feces in dysentery by several authorities before Lösch, it is generally conceded that to him belongs the credit of having first adequately described them, and to them he gave the name *Amoeba coli*. Since his original article, numerous observers have tried to separate and classify varieties of amoeba and some authorities have designated

Schaudin found that nuclear division of a regular character is not observed in *Amoeba coli* (*Entamoeba histolytica*); instead a fragmentation of the chromatin takes place, the remnant of the nucleus being expelled from the parasite. After this division of the chromatin, small spheric bodies are formed, each presumably containing some of the chromatin. He showed, experimentally, that these spores were capable of causing serious intestinal symptoms and lesions. He also gives, as one of the differential characters between *Amoeba coli* and the amoeba found in the healthy intestine, the sharp differentiation of the outer protoplasmic zone from the inner, which, being of much firmer consistence, enables the dysentery amoeba to work its way into the mucous membrane. This I have not been able to confirm in all cases.

Since writing the article alluded to, I have tried many methods of staining the amoebæ in order to demonstrate, if possible, the formation of spores. It was not until very recently that I have been able to do so. The method I have succeeded with was suggested to me by Dr. H. R. Oliver, of this city, for malarial parasites, and is generally known as "Wright's method." Dr. Oliver has made some modifications in this stain which increases its value very much, and with it I have been able, I believe, to trace the evolution of the amoebæ from the young form to the fullgrown spore-bearing stage. A detailed description of the method will be given in a later and more extensive contribution.

In the examination of 748 cases of amoebic dysentery at this hospital (in which the feces contained amoebæ), in soldiers returning from the Philippine Islands, I have time and again noticed the small, oval, refractive areas described in my original paper and have always believed them to be spores. I have repeatedly seen large round amoebæ filled with these oval bodies, arranged in rows in a perfectly symmetric manner, the organism appearing to be crowded with them. If the parasite were moving it was noticed that these oval areas seemed to be contained within the protoplasm with which they moved, but they could easily be differentiated from the larger or smaller vacuoles. They were uniformly of the same size, whereas the vacuoles differed in size, and it was seldom indeed that vacuoles were present in such amoebæ. In fact, I am firmly of the belief that vacuolization is a degenerative process in *Amoeba coli*.

Amoeba coli.—In specimens stained by the modified Wright's method, the structure of *Amoeba coli* is colored as follows: The ectoplasm is stained a dark blue, or nearly purple; the endoplasm a light delicate blue; and the chromatin of the nucleus a dark red. In specimens stained in this manner the following varieties of amoebæ are observed:

1. Small amoebæ having a deeply stained ectoplasm and dimly stained endoplasm, and a large sized collection of chromatin, generally situated at one side of the parasite, within the endoplasm.

2. Slightly larger amoebæ colored in the same manner, but showing a division of the chromatin into two nearly equal portions. The chromatin in both of these forms upon careful examination is seen to consist of very delicate fibrils and dots, arranged in a more or less definite manner.

3. Larger amoebæ colored in the same manner, but showing a further division of the chromatin into numerous small clumps, varying in number from 6 to 12 or 14. These clumps are arranged irregularly throughout the protoplasm (within the endoplasm) of the amoebæ and the chromatin seems to be collected in a compact and more deeply staining mass.

the amoeba of dysentery as "*Amoeba dysenteriae*." According to the "law of priority" mentioned, the name *Amoeba coli* should stand, and those authorities who have changed it have, I believe, only further confused the classification of these organisms, and have been unjust to Lösch, the original investigator. It will therefore be understood that I have adhered to the name *Amoeba coli* as designating the amoeba of dysentery.

4. Amœbæ of the same size showing apparently the same number of chromatin collections, but the chromatin surrounded by an unstained interval in the endoplasm of the amœbæ and arranged somewhat regularly. The chromatin collections are smaller, more compact, and stain very deeply, are oval in form, and are of exactly the same size.

The last form mentioned is never as large as the amœbæ containing numerous vacuoles, and would be considered ordinarily as a medium sized organism. Measurements and the finer details of the structure will be considered in a forthcoming contribution. The figures show diagrammatically the various forms described.

The amœbæ containing these bodies do not appear to

Figs. 1 to 6.—Sporulating cycle of *Amœba coli*. Fig. 1.—Amœba, showing deeply stained ectoplasm (b); dimly stained, granular endoplasm (c); nucleus, with chromatin, deeply stained (a); vacuole (d); and engulfed bacteria (e). Fig. 2.—Showing division of chromatin mass into two portions (a); at b is seen an engulfed foreign body. Fig. 3.—Showing division of chromatin into the somewhat irregular masses which stain very deeply. Figs. 4 and 5.—Sporulating amœbæ. In Fig. 5 the process is complete, the young spores being arranged somewhat regularly and staining very deeply. Figs. 6 to 8, inclusive.—Nonsporulating forms of *Amœba coli*. Fig. 6.—Large amœba, showing vacuole (c), nuclear chromatin (a), and numerous red blood corpuscles. Fig. 7.—Large amœba, showing numerous vacuoles (b) and the nuclear chromatin (a) distributed in strands throughout the organism. Fig. 8.—An amœba, showing nuclear chromatin (a) and engulfed bacteria (b).

be encysted, as I have not been able to detect any distinct cyst wall, the border of the amœbæ appearing as it does under ordinary circumstances, save that in the last form mentioned the ectoplasm is hardly distinguishable. In interpreting these appearances, I believe there can be only one explanation, and that is, that these divisions of the chromatin, which afterward become arranged regularly throughout the organism, form a portion of the nucleus of young spores, and in several instances I have been able to differentiate a narrow zone of pale-blue protoplasm surrounding each clump of chromatin, thus demonstrating the outline of the spore. In other words, these spores consist of a clump of chromatin lying, probably, in an unstained nucleus and surrounded by a small amount of protoplasm.

The only step in the evolution of these organisms, as shown in the stained specimens, which has been missed, is the actual rupturing of the amœbæ and the setting free of the spores. While I have seen amœbæ which appeared to have ruptured and the clumps of chromatin distributed outside of the organism, I am of the opinion that this was probably accidentally due to the preparation of the smears, but I have no doubt that such a setting free of the spores occurs in the intestine.

The following forms of amœbæ also occur in the specimens and should be carefully distinguished from the sporulating bodies.

(a) Large amœbæ containing numerous vacuoles, many of them appearing to be nothing more or less than a thin shell of protoplasm entirely riddled by the vacuoles. In these amœbæ the chromatin is reduced greatly in amount, and stains very dimly. It is also distributed very unequally throughout the endoplasm, and never in the round or oval clumps seen in the sporulating bodies. These amœbæ are undoubtedly degenerating bodies, as vacuoles seldom occur in the sporulating forms.

(b) Amœbæ of various sizes showing within their protoplasm numerous very darkly stained bodies of a deep purple color and of various shapes. At first sight these bodies might be taken, in many instances, for spores, but in reality are bacteria which have been engulfed by the amœbæ.

A peculiar fact, the interpretation of which I am not sure of, is that I have never seen any red blood cells within the sporulating amœbæ. It is probable, however, that before sporulation occurs any cells which have been so enclosed are thoroughly disintegrated.

From the foregoing observations, I believe that it is demonstrated that *Amœba coli* undergoes reproduction by sporulation, and that this manner of reproduction most adequately explains the persistence of amœbic infections. If these sporulating bodies are in reality encysted this would still further explain the persistence of such infections, as encysted parasites are more resistant to injurious influences.

In closing, I would call attention to the efforts which have been made to separate amœbæ into species, some pathogenic and some nonpathogenic. It is unnecessary to give in this preliminary note the classifications which have been made by various authorities, in which they endeavor to show that the amœba of dysentery, or *Amœba coli*, is a distinct species, and that it differs widely from amœbæ occurring in the healthy intestine of man, or other animals. The chief points which have been urged as differentiating *Amœba coli* from other amœbæ, are the following:

1. *Size*.—Some authorities, especially Strong,⁶ classify amœbæ into small or large amœbæ—the large being the amœba of dysentery. These authorities state that in specimens it will be observed that most of the amœbæ are of the same size, and that in cases of amœbic dysentery the preponderance of large amœbæ is very noticeable. From personal experience, I cannot confirm this observation. Careful examination of the feces will show that amœbæ of large size are not always present in dysentery, and while it is often true that any given case will show a preponderance of amœbæ of the same size, careful examination will also show that many much smaller and larger than those most numerous are present. To classify amœbæ, because some are larger than others, into distinct species, is not possible. Amœbæ, like other parasitic organisms, have the property of growth, and we would naturally expect to find amœbæ of various sizes in any given specimen. The fact that a greater number are found approximating each other in size only tends to prove that the reproduction of the parasite occurs at a definite period of time, just as in malaria. While many cases show a preponderance of very large amœbæ, others show the same preponderance of small, and, so far as the clinical symptoms are concerned, these cases cannot be differentiated. Not infrequently a case

of amoebic dysentery will be observed in which the amoebæ present are all smaller than those usually found. In these cases, however, the clinical symptoms of the disease are the same.

2. *Phagocytic Action.*—Some authorities have endeavored to classify amoebæ by observing their power of phagocytic action, claiming that only in the amoeba of dysentery does such action become pronounced and that the property of engulfing red blood-corpuscles is peculiar to this variety. From my own experience, a classification based on so small a point is unwarranted, as it may be said that all amoebæ found in the feces possess this property. Many instances are seen in which nearly all the amoebæ in a given specimen show red corpuscles within them, while in other specimens such amoebæ cannot be demonstrated. This does not prove anything, however, as the process is in all probability a natural one in the evolution of the organism and depends upon the amount of blood in the stools and unknown factors.

3. *Occurrence of Amoeba in Health.*—The strongest reason for the classification of amoebæ into pathogenic and nonpathogenic varieties is, without doubt, the occurrence of these parasites in the healthy intestine without producing symptoms of disease. The strength of this argument is, however, only apparent. As regards the occurrence of amoebæ in the stools of an apparently healthy individual, no one who has had experience with amoebic dysentery will deny that occasionally cases are observed which show amoebæ in the stools, and in which there are no clinical symptoms. To use these cases, however, as an argument for the existence of a nonpathogenic amoeba inhabiting the human body, is absurd. One might as well argue that the cholera spirillum does not cause cholera because it has occasionally been found in the feces in healthy individuals, or that malaria is not due to infection with the malarial parasites because they may be found in the blood when symptoms of malaria are not present.

All will admit that there must be, at some time, a period in which the amoebæ will be present in the intestine, even in those cases that afterward develop severe dysentery, without any symptoms being appreciable. In other words, there must be a period of incubation, and this period of incubation may extend over a long interval so far as we know. This would coincide with our knowledge of other infections, and if we consider for a moment the long latent period after infection and before malarial fever demonstrates itself, we will, I think, be forced to believe that there must be a considerable interval of time from the infection of the intestine with amoebæ before the outbreak of dysenteric symptoms. We do not know, as yet, the interval required for the evolution of this parasite. This may cover a long period of time. It is also evident that there must be an infection with a sufficient number of the parasites, in order to produce symptoms. Taking these facts into consideration, then, is it at all to be wondered at that amoebæ are found in the stools of apparently healthy individuals, but is it not a greater source of wonder that they are not more often found.

That amoebæ are present in such cases, only proves to my mind one of three things, either that the individual harboring them is not infected with a sufficient number or for a sufficiently long time for them to cause symptoms, or that he is immune to the effects of the organism, or that the organism itself has lost some of its virulence. The loss of virulence, however, does not transform one species of parasite into another. Amoebæ occurring in the apparently healthy intestine are, so far as I have been able to observe, identical with those occurring in dysentery; and the endeavor to classify these organisms as pathogenic and nonpathogenic, in the case of infection in man, will only lead to confusion and is of little practical importance.

MEDICAL TREATMENT OF DIABETES.¹

BY

W. H. THOMSON, M.D., LL.D.,
of New York City.

The pathology of diabetes mellitus has been the most elusive problem of modern medicine. Repeatedly during the past 40 years we have seemed to be on the verge of important discoveries relating to it, only to find that our uncertainties, instead of being dispelled, had simply taken new forms, which in turn have raised other problems to solve.

It is, of course, due to the great obscurity resting upon the physiologic mechanism for the disposal of the carbohydrates of food in the system, that the pathology of diabetes has remained so uncertain. Fifteen years ago, in a symposium like this, held at a medical gathering in New York City, I suggested that we were yet without any knowledge of a seemingly important factor in the problem, and that was the relation of the muscular tissues to the utilization of the saccharin elements of food. The facts which we did know then were that the muscular tissues were virtually the chief generators of animal heat, and that quite apart from their function of contraction and of relaxation, was their function of oxidation, so that the blood collected from the veins of a large muscle like the gluteus, though the muscle were at perfect rest, yet contained less oxygen and more carbon dioxid than the blood of the right ventricle itself, as this latter was mixed with blood from the great glandular viscera where oxidation is less active than in muscle. This shows how much burning up of blood contents occurs when the blood is coursing through muscular tissue, and as the chief material for such oxidation consists of carbohydrates, some failure in this muscular function might have much to do with the pathologic failure of sugar oxidation in diabetes.

This suggestion was received with incredulity, and most of the speakers confined their attention to the supposed relations of the nervous system and of the glycogenic functions of the liver to this disease. Not long afterward the pancreas in its relation to diabetes came to the front and has maintained its place as one important factor in the problem ever since. Lately the news comes that O. Cohnheim finds that an enzyme is produced in muscle, which if alone does not act upon sugar, but when mixed with the secretion of the pancreatic cells of Langerhans is a very energetic solvent, in the same way that trypsin becomes effective only when conjoined with the kinaise ferment in the intestine.

Until physiology becomes settled, pathology cannot be settled; and, therefore, therapeutics, while matters so stand, must remain mainly empiric. And so I confess that I regard the subject of medical treatment of diabetes, which has been assigned to me, one to which I can contribute little beyond the results of my experience, based upon written notes of the histories of patients whom I have treated in the course of years.

To the question, When does glycosuria mean diabetes? my answer is that we do not know. That glycosuria, limiting that term to dextrosuria, is an epiphenomenon, appearing in the most diverse connections, we all know. Like albuminuria, it occurs too often and too variously as a temporary accompaniment of different disorders to be rated as no more frequently than a

¹ Read before the ninety-eighth annual meeting of the Medical Society of the State of New York, held at Albany, January 26, 27, 28, 1904.

symptom. In the case, however, of albuminuria we usually can form some conception of its causation. But with glycosuria we do not know whence it cometh, nor whither it goeth; and, therefore, we can never be sure what its significance is. Hence I feel sceptical about the assurance with which some pronounce, offhand, a given case as one only of glycosuria, and another as surely diabetes, because in my experience, some patients come with both a moderate and an intermittent presence of sugar in the urine, and with no constitutional disturbance, but who in time develop into confirmed diabetics, while others may come with very saccharin urine and severe constitutional symptoms, only to improve under treatment and finally get well. Nor does the recent date of the disorder make much difference. Some begin suddenly, and soon develop grave symptoms, and then become permanently free from their trouble, while others begin just as suddenly and never get well. The only valid distinction which I admit is that the presence in the urine of diacetic acid, shown by the ferric chlorid test, is generally indicative of confirmed diabetes.

My practice, therefore, is to pronounce a glycosuria which has lasted more than a year, diabetes. Time, in other words, and not the variability either of the glycosuria, or of any other accompaniments, is my ground for diagnosis. Persistent glycosuria, in its way, is much the same as persistent albuminuria in its way, that is, each means that the patient has a serious disorder; and *pro tanto*, it does not much matter what name we choose to tack to the disorder when the question is how we are to treat it.

As it is the patient, and not his named disease, which is to be dealt with, all factors entering into his story have to be taken into account; and the first of these facts is age. The rule is, the younger the patient, the worse it is for him. Why it should be so, I do not know. The chief significance of this fact, however, is that it points to diabetes as a deeply seated constitutional disorder, and not a localized disease of any one organ, pancreas or other. In keeping with this inference, is the hereditary or family proclivity to the disease in instances too numerous to be accidental, and equally so the greater liability of certain races to it. In my experience there is no race so subject to diabetes as the Jews. The bearing of these clinical facts upon what remedies we are to expect the most from, and also what reputed remedies we are not to expect much from, we will soon note.

The next consideration to age is the state of the nutrition of the patient. I always make it a point to determine what the daily output of urea is, as well as the amount of sugar passed. If the percentage of urea is continuously high, there is real emaciation going on, even if the patient be fat. The sugar itself, indeed, may disappear, but the urea excretion remain one-half more or double what it ought to be. The patient must have medicines for that.

The patient may be obese. This condition calls for special medication on account of danger from the heart. If he has oxalates alternate with abundant uric acid crystals in his urine, all the better for him. He may be a profitable patient to us for years, though, *pace* glycosurists, he should not be allowed to forget that he has diabetes—and so on. All I wish to illustrate by this preface to my subject, announced on the card as "Medical Treatment of Diabetes," is that I would prefer to have it read, "Medical Treatment of Diabetic Patients."

As to medicines, I would begin with the statement that I but rarely prescribe opium, codein, or any other of the opium derivatives; and I beg leave to take a short time to explain why, in such a constitutional disease as diabetes, I cannot regard this drug as of real service, though it has been long and generally recommended in textbooks. Nervines, such as opium, belladonna, strychnin, aconite, etc., are agents which affect certain functions of the nervous system. They,

therefore, are only functional remedies, and they have no power whatever in therapeutic doses to affect structure or nutrition directly, however long they be prescribed. All that they ever do is temporarily to produce some functional symptoms, but they never affect the texture or the nutrition of tissues of organs, either beneficially or injuriously. Therefore, none of them can touch diabetes itself, any more than they can touch typhoid fever. However, some of them may relieve for a time some serious symptoms in both diabetes and in typhoid fever. As a veteran teacher of materia medica, I used to urge that no functional or symptom medicine, such as the nervines, could be expected to modify an organic disease in any way, either for good or evil. The only exception being in the case of colchicum,¹ which can produce organic changes. Alcohol produces organic changes only by virtue of its chemic and not by its nervine properties. One of the most powerful nervines for properties is nicotin. There is a great deal of functionally active nicotin in a cigar. Let any one who has never smoked a cigar, try it, and he will soon illustrate what nicotin can do. Now my father, my grandfather and my great-grandfather began to take nicotin, by smoking tobacco, about the same time of life that I did, namely, at 12 years of age, and continued the same to the last year of their lives, which was at the ages of 88, 87 and 92, respectively, while I am well on to my three score and ten. Can nicotin, therefore, not injure the bodily mechanism? Never, in rational doses, for like all other nervines, in such doses it can neither do permanent good nor permanent harm.

To this class of functional medicines belong opium and its derivatives; and, therefore, diabetes continues progressive, however continuously or fully opium is prescribed. A functional medicine is one whose whole action can be secured by one dose. Its hundredth dose does not do any more than the first dose does, sometimes not as much, for with many of this class, as with tobacco, the system becomes used to them. A man may for many years relieve an asthmatic attack by stramonium, but it is not his disease—asthma—which is thereby dealt with, but its symptom, bronchial spasm, and his last dose of stramonium does not do more for him than the first dose did, taken years before. More efficacious against his asthma itself would be arsenic and potassium iodid, which no more act in one dose than mercury does in syphilis, or iron in anemia. The fundamental difference between functional medicines, which influence only functions, and organic medicines, which change the nutrition of tissues or organs, would be more widely recognized but for the confusion which exists in many minds about the term "function." Because function is deranged whenever organism is deranged, therefore, it is supposed that the converse of this statement is equally true, namely, that a derangement of function must always imply a corresponding derangement of organism. A simple illustration will show the difference. The function of an oil lamp is to give light. Derange the mechanism of the lamp, by a leak in the globe, or by an injury to the wick holder, or by the loss of the wick, and the light-giving function of the lamp is correspondingly deranged. But the entire mechanism of the lamp may be perfectly intact, and yet it will give no light because the source of its function, namely, the oil, is changed by mixing it with water. So, a steam engine may be perfect in every detail of its mechanism, and yet not go, because the source of its function, namely, the coal, is lacking. So in the living mechanism, its func-

¹ Dr. Norwood of Alabama, well known for Norwood's Tincture of Veratrum Viride, narrated to me how 5 young men in his neighborhood, while on a "spree," broke into a country doctor's office, in the doctor's absence, and drank to his health out of a bottle of wine of colchicum, which they mistook for sherry. Two of them died, but Dr. Norwood saw the survivors a number of weeks afterward, when they had lost all their hair, including their eyebrows, and were as generally yellow as persons recovering from cobra snake venom. Now, recovery of healthy persons from the most dangerous degrees of poisoning by opium, belladonna, aconite, etc., is generally complete after 24 hours, with no lasting nutritional change whatever.

tions need power therefor, and that power is in the blood. Functional medicines act only on and through the blood, and not on the tissues. This being so, functional medicines can act only temporarily, they have to be renewed just as the oil in the lamp has to be renewed, though the lamp itself remains the same indefinitely. The oil can remedy no injury to the mechanism of the lamp, and likewise every functional medicine is powerless against a truly organic injurious change going on in the living mechanism.

Functional medicines we need constantly in practice to relieve symptoms, or to meet emergencies. They are indispensable for such purposes, but we should always remember that all which a functional medicine can do is to deal with a temporary derangement, not in the structure, but in the working, that is, in the function, of the body; and this it does immediately in one dose. But no specifically permanent changes should be expected from it. Opium may affect the symptom, sugar in the urine, by temporarily diminishing it, but it has no effect upon the disease which causes that symptom.

We must look elsewhere in such a constitutional disease as diabetes than to such functional medicines as opium, and I notice that of late, experience is leading many physicians to abandon its use in this malady. For a number of years I have advocated the free use of cod-liver oil in diabetes. I was specially led to do this by its remarkable effect in the case of 2 brothers whom I treated 32 years ago.

The first, an active business man, aged 35, came to me with polyuria, thirst, emaciation and progressive loss of strength, for which he had been treated unavailingly for a year, with the usual course of diet and drugs. He then took larger doses of cod-liver oil than any patient in my experience, for he said that he never measured it, but took it directly from the bottle as a drink, followed by vichy water. In another year's time he was cured, and he has remained well ever since.

His brother, 2 years younger, came to me the following year with much the same condition, so far as the great quantity of sugar in the urine was concerned, but he suffered in addition from general bronchitis. He found that he could stomach cod-liver oil as well as his brother, and with equally good results.

The younger the patient, the more persistently I urge the taking of this remedy, and I adopt every resource to make its free use possible by the patient, by the administration with it of pepsin and bismuth. So long as the stomach does not rebel, diabetic patients of this class cannot take too much cod-liver oil. Whether this oil acts as a substitute for the starchy elements, or whether it spares the proteids from disintegration, or whether it acts as a nerve food, or whether it acts by increasing the red corpuscles, I do not know; but as an empiric fact, I can testify that it both diminishes the sugar and the excess of urea eliminated whenever it is taken freely and is well borne. As in all cases, in which we aim at influencing nutrition by any measure, it must be used both systematically and perseveringly. Obesity counterindicates it, and likewise I would not give it to patients of very sedentary habits; but it is quite useful with many elderly people.

Next to cod-liver oil, I would mention iron. As before remarked, I have long suspected diabetes as largely a muscle disease, and throughout the animal kingdom muscular power is directly proportioned to the intake of oxygen. As iron can act in us only in its capacity of an oxygen carrier, I try to give diabetics all the iron which they can take, along with all the fresh air which they can get. As iron in many forms tends to cause constipation, which itself not infrequently becomes a serious trouble to diabetics, a very serviceable preparation for them is the old-fashioned Hooper's pills, the formula of which is:

Ferrous sulfate	2 gm. ($\frac{1}{2}$ dr.)
Powdered senna	} of each . 0.8 gm. (12 gr.)
Powdered jalap	
Cream of tartar	
Powdered ginger	
Extract of gentian	A sufficient quantity
Divide into 30 pills.	

The progress of medicine in our time has added a class of remedies which is coming more and more into daily use, and to which I would apply the term *medicinal*, in distinction from *surgical*, antiseptics. It includes a varied list of phenol derivatives, among which I would include quinin, for sooner or later we may look for its synthetic production from coal-tar, as well as the salicylates and the benzoates. In this class of medicinal antiseptics I would also include arsenic.

It is not improbable that one of the properties of this class of medicines is to check the activity of various enzymes, which in particular states cause derangement of metabolic processes in the body, or lead to disintegration of its tissues. We are only beginning to get some insight into the relations which certain internal secretions bear, on the one hand, to the assimilation of food, or on the other, to the neutralization of poisons in the system, or to the disintegration of the tissues themselves. One of the most striking facts in this connection is the singularly small quantity of the secretions themselves which seems to suffice to maintain the important functions which they subserve. Thus the total extirpation of the pancreas in dogs induces a fatal diabetes. This diabetes is ascribed to the removal of the scattered glandular structures in the pancreas, called the "islands of Langerhans." But if three-fourths of the pancreas be excised, so that only one-fourth remains, the small remnant of these island cells is yet enough by their secretion to prevent glycosuria. This indicates that this internal secretion is of the nature of an enzyme which can propagate its action from very small beginnings. The small bodies, called the parathyroids, have recently been proved to be essential to life, owing to their internal secretion neutralizing a virulent poison, generated most probably in the alimentary canal, and which poison causes fatal tetanic convulsions. So excision of three-fourths of the kidneys, leaving only one-fourth of kidney substance, is followed by death, preceded by great polyuria, with such excessive excretion of urea that it seems as if the proteid tissues were undergoing rapid dissolution. This remarkable result is ascribed to the kidneys having as their function not only to excrete, but also to regulate the production of urea by an internal renal secretion.

However that may be, I have for some time been much interested with cases which have come under my observation, of excessive excretion of urea which, in a way, resemble saccharin diabetes.

On December 5, I was consulted by a healthy looking young man, aged 23. He seemed to be a typical neurasthenic, for his complaints were that 2 years ago he had a sudden nervous breakdown, ever since which he could not apply his mind to anything. He has a constant sense of fatigue, is very nervous and dyspeptic, especially intolerant of starchy food, and very insomniac. His pulse was soft and weak. Examination of his urine showed that he passed no less than 51 grams of urea a day, while according to his size and on his restricted diet, he should normally pass only 22 grams. The total solids of the urine amounted to the high figure of 114.37 grams, or 1,715 grains. There was no albumin, nor casts, nor sugar, obtainable by any test in the urine, and he had no fever. His family history was decidedly unfavorable in the respect of neuroses, one brother is in an asylum, an elder sister has something like cyclic insanity, and another sister—younger than himself—is abnormally fleshy.

I put him on the same treatment that I would a diabetic, namely, a shellac-covered capsule, containing .32 gm. (.5 gr.) of sulfocarbonate of soda, and 65 mg. (1 gr.) of potassium permanganate, to be taken a half-hour after meals and at night; and 1 hour after meals 3 times a day, a powder of .6 gm. (10 gr.) of sodium salicylate and .6 gm. (10 gr.) of sodium benzoate. On December 16 he came again, remarkably improved in all his symptoms. His urea had fallen from 51 gm. to 30 gm., and the total solids had decreased 250 grains. To add now .6 gm. (10 gr.) of aspirin to each dose of the sulfocarbonate, or 2.6 gm. (40 gr.) per diem. On January 16 he reported that he was able to do more work than he had done for some years, and that he was now studying to pass a university examination.

I believe that if physicians, instead of being content in their examinations with discovering whether there were abnormal ingredients in the urine of patients, would also uniformly investigate whether the normal ingredi-

ents were present in their healthy proportion, that more cases of this kind would be found than are generally suspected. What special process led to such abnormal waste in this patient, I do not know, any more than what the real processes are which underlie the disease diabetes. The processes of the chemistry of life are altogether too complex, and too imperfectly understood as yet, for us to make more than doubtful guesses. But as an empiric fact, I am sure that I succeed better in controlling diabetes mellitus, so far as the use of drugs goes, by a persistent and free administration of antiseptics than by any other means, cod-liver oil and iron excepted. In such a disease the therapeutic tests should be sought for only in severe and prolonged cases; and I will beg leave, in illustration, to cite briefly one such history.

He was a gentleman of 42, who, after a year of severe mental strain noticed that he was passing water very often, and that his shirt when wet by the urine was stiffened by it. He was put on diet, opium and codein, by his physician; but as he was steadily losing flesh and strength and was subject to alarming attacks of syncope he finally consulted me. I first saw him after one of these attacks. He was cyanosed and extremely dyspneic. Another attack soon occurred in which he seemed to be passing into diabetic coma. For 16 years after this, I conducted the management of his case, watching him very closely as he was a most intimate friend of mine, and though I never found sugar absent from his urine, during those 16 years heabily performed the exacting duties of chief editor of one of the largest of New York's daily newspapers. He then moved to another city, to enter upon a much less exacting business. I warned him that he was by no means a well man, and that he should continue his treatment without change. I learned, however, that he became quite careless, and in 3 months he succumbed to an attack of bronchitis.

Such histories of years of active life, while keeping up treatment, soon followed by fatal decline on cessation of the same, have occurred more than once in my experience. Nature does not cure diabetes.

As remarked before, I would include arsenic in this class of antiseptics, as it comes nearer in its properties as a medicine to such agents than to any other. My usual practice is to combine it in the same prescription with them, and, therefore, I ordinarily give arsenious acid, itself, watching for the development of arsenial symptoms, just as in prescribing it for any other purpose. Some of the liquid preparations, as Fowler's solution, liquor arsenici hydrochloricus, or the bromid of arsenic have the advantage that the dose may be increased or decreased more readily, but I have failed to note any special advantage in changing the form of the drug, because it is arsenic itself in them all to which the effect is due. As to the rest, their administration should be varied from time to time, on the general principle that the too continued use of any drug tends to lessen its efficacy, or in the case of the salicylates to irritation of the kidneys. If called to a patient who is voiding so large an amount of sugar that a speedy reduction of it is imperative, I would give 1 gm. (15 gr.) of antipyrin, with the same of sodium benzoate, 4 times a day. After a time I would substitute 1 gm. (15 gr.) of aspirin with .65 gm. (10 gr.) of bismuth salicylate. In subacute cases, illustrative prescriptions would be somewhat as follows:

Benzosal	3 gm. (48 gr.)
Sodium benzoate	.16 gm. (4 dr.)
Arsenious acid	.65 mg. (1 gr.)
Sodium salicylate	.11 gm. (3 dr.)

Divide into 48 capsules. Two an hour after meals and at night.

Sodium sulfocarbolate	8 gm. (2 dr.)
Salicin	4 gm. (1 dr.)
Phenacetin	8 gm. (2 dr.)
Ammonium benzoate	.16 gm. (4 dr.)

Divide into 48 capsules. Two, a half-hour after meals. If there be much insomnia 1.3 gm. (20 gr.) of strontium bromid and 1 gm. (15 gr.) of antipyrin at night.

Of course, each physician can vary such medication according to indications. A weekly dose of blue pill is nearly always beneficial to patients after middle life. Unless the patient be much emaciated, one of the means

which works well to prevent the tendency to constipation is a powder dissolved in a tumbler of hot water and sipped slowly on rising, of 6 gm. (1½ dr.) of sodium bicarbonate, 2 gm. (½ dr.) of sodium sulfate and of magnesium sulfate each, and .65 gm. (10 gr.) of sodium salicylate.

Alkalies, in the form of mineral waters, have always held a deserved place in the treatment of diabetes. There is, however, one caution to be always borne in mind, and that is, that the free use of all saline waters tends to increase the waste of the system, and they should not be given to any one who is really losing flesh. I think that I have seen them do harm to emaciating diabetics.

Diabetes is a very serious disease on one account alone, if not on other accounts, in that it virtually compels a starvation of an essential element of food. The system must have sugar, and if it does not get the sugar which it can use in the food, it will turn to its own proteid for sugar. Along with this profound perversion, poisons begin to be generated, of which oxybutyric acid and its derivatives are doubtless only a part, and which poisoning we are practically unable to neutralize. Our function, therefore, is to put off the evil day of these terminal developments as long as possible, and to do that I am sure that merely functional medicines will afford us no help. The essentials of the chemistry of this specific toxemia are yet unknown. The formation of acetone and of diacetic acid occurs early, and the blood itself often changes its color, owing to the abundant presence in it of fatty and of proteid granules. Something, however, holds back the carbon dioxid in the tissues, for it is a mistake to ascribe the low percentage of carbonic acid in the blood to hyperacidity, because the blood of those patients when drawn will take up oxygen or carbonic acid about as freely as normal blood. The last step is the rapid disappearance of sugar from the urine. Why sugar is absent in diabetic coma, we do not know, but curiously enough the first danger signal comes from the kidneys, for before drowsiness begins the urine often deposits an enormous number of peculiar looking casts. To postpone the wellnigh inevitable death in these conditions, I rely upon the most trustworthy diuretic which we possess, namely, prolonged intestinal irrigation with hot normal saline solution, by means of the best instrument for the purpose which I know of, Kemp's rectal irrigator. Hypodermic injections of .45 gm. to .9 gm. (7 gr. to 14 gr.) of camphor in sterilized almond or olive oil, answer best to sustain the failing heart, while diluted milk holding all the sodium bicarbonate which the patient can take, is the only recourse left for food. Some of the fatal poison doubtless could be washed out, if we could bleed the patient freely and transfuse an equivalent amount of normal saline.

THE RETINAL SYMPTOMS OF VASCULAR DEGENERATION.¹

BY

L. A. W. ALLEMAN, A.M., M.D.,
of Brooklyn, N. Y.

In the routine of daily practice the efforts of the physician are chiefly directed to the relief of 2 groups of cases, one the result of the action of some pathogenic organism, the other dependent on derangement of the complicated mechanism of bodily nutrition.

While we must relieve the immediate and urgent distress of our patients, the trend of modern medicine, the goal toward which investigators all over the world are directing their efforts, is the prevention of disease, and it is not unreasonable to expect that in the near future protective inoculation will provide immunity from zymotic diseases; but for the disorders of nutrition,

¹ Read before the Brooklyn Medical Club, October, 1902.

for those degenerative changes, which sooner or later must destroy the human organism, we may hope for no specific.

It is difficult to isolate the bacillus of old age. The antitoxin supposed to flow from the fountain of youth has eluded the modern student, as it did the old explorer and alchemist.

That "a man is as old as his arteries" is one of those propositions so self-evident that it is never questioned. Perhaps, for that reason, it is given less serious consideration than it deserves. While we feast, time is writing clearly on our walls, but, like Belshazzar, we can find no interpreter to translate the warning 'til the enemy is at our gates.

It is well known that in cases of advanced vascular disease we can, by the aid of the ophthalmoscope, recognize the condition, in some instances, before any general symptoms are manifest, but unfortunately for the patient, the discovery is of little value save to give him an opportunity to put his house in order.

If, however, we can by an inspection of the fundus oculi detect those functional changes which must precede the organic and irreparable, we have added to our resources a most valuable means of diagnosis, and one which will enable us to give advice of incalculable value to our clients.

I believe in many cases such information can be

Fig. 1.

obtained by the ophthalmoscope, and I wish to discuss some clinical findings, which, I think, support this contention, and to ask aid in digesting the material I have collected and in determining its true scientific value.

My attention was first directed to a study of the minute changes in the retinal circulation by a paper read by Dr. Ole Bull, before the Ninth International Medical Congress. In this most valuable article he lays special stress on the occurrence of a spasm of the retinal vessels, which he shows to be the cause of some of the obscure ocular manifestations for which we have no other satisfactory explanation.

In endeavoring to verify his observation, I learned that such cases of vascular spasm were not uncommon, and also that localized and transient contractions took place in the retinal vessels; in the cases presenting this symptom there were other slight departures from the normal which were found in association with sufficient frequency to constitute a reasonably distinct clinical picture.

It naturally suggested itself to me to inquire closely into the physical condition of the patients presenting these symptoms, in order to ascertain whether the ophthalmoscopic findings were an index of some corresponding condition in the general economy.

The collection of sufficiently reliable data to deter-

mine this point proved to be no easy task, for there is, among the laity, a class possessed of just sufficient intelligence to acquire and use glibly certain medical phrases and to develop medical theories, yet wholly incapable of appreciating their own limitations. They are always ready with an off-hand opinion upon any case, which they deliver with a positiveness which would put to shame the most experienced practitioner. One of the dangerous half truths, which has impressed itself upon many of these people, is the belief that Bright's disease can always be detected by the ophthalmoscope, and as

Fig. 2.

it chanced, in my practice, that interesting retinal pictures were frequently found in the eyes of these lay doctors, you can imagine the complications which arose. The suggestion of a physical examination, after an inspection of the eyeground, was taken as a death warrant, despite my solemn assurance to the contrary, and would precipitate a visit to the family practitioner, with the statement, made in wild-eyed terror, that I had said they had Bright's disease. A hasty examination in the office would enable the doctor to reassure them; the result was that if they ever returned to me, it was to

Fig. 3. (Normal.)

confront me with the statement that I was entirely mistaken in my opinion of their case, and naturally I learned absolutely nothing of value as to the patient's condition.

Such experiences are unfortunate, both for one's temper and professional reputation. I did, however, finally secure sufficient material to form a basis for some deductions, and for convenience I will divide the cases, which we will discuss into 4 groups, which in practice shade insensibly one into the other.

In the first group of cases no organic lesion is discover-

able by the ophthalmoscope, and the important finding is a tortuosity of the smaller retinal vessels, and of their terminal twigs.

This is not the sinuous curve which is seen in neuroretinitis and papillitis, and to a less degree in some cases with an uncorrected error of refraction, but a crinkling and sharp turning of the vessel upon itself, which I have endeavored to illustrate in Fig. 1; there is usually associated with this some slight retinal haze, probably due to edema.

No indentation at the point where one vessel passes over another is seen, nor is the vessel wall visible.

In the second group of cases a similar condition of the fundus is found, but in addition more or less bending of the vessels at the crossings is present. (Fig. 2.)

Under normal conditions, save possibly in the aged, one retinal vessel passing over the other gives such a picture as would be seen were the vessels flat red bands, both vessels occupying apparently the same plane (Fig. 3), but when the vessel wall becomes unduly rigid the upper vessel is seen to rise from its level and bend as it passes over the lower; in the stage which we are now considering, the upper vessel, while curved, still appears simply as a red line, and no obscuration in the lower vessel is produced by the coats of the one above.

In many of these cases a change in the caliber of the retinal vessels is observable; this is not an encroachment of the thickened vessel wall upon the lumen of the vessel, nor is it due to an opacity in the coat of the vessel. It is localized diminution in the caliber of the vessel without other change, visible by the ophthalmoscope. The condition of spasm to which I here refer is not one involving the whole central artery of the retina, or its main branches, thus producing retinal anemia and consequent visual disturbances, but is confined to small areas, which suggests that a contraction is produced by some disturbance in the local vasomotor control. While in many cases the constrictions in the vessel can always be observed, in others they are a transient symptom; they do not remain constantly at one point, but come and go, frequently changing their location during an examination. There is another retinal symptom which may be mentioned in this connection sometimes seen in this group of cases, although not directly dependent upon eliminative disturbances. The condition to which I refer is a momentary decrease in the force of the retinal circulation.

While the phenomenon is by no means uncommon, it is one not easily studied, for the change in the retinal picture is so transient that it does not permit the inspection of a vessel during its occurrence.

Ophthalmoscopically, it gives one the impression of a flash, you know something has happened, the exact nature of which you are unable to determine, but I consider this symptom of great clinical value, for I have always found it associated with deficient force in heart action, usually without organic lesion, as a rule, in anemic and neurasthenic patients; there is sometimes a functional murmur present, with some disturbance of the force and rhythm of the heart's action, and the retinal picture probably results from a momentary emptying of the retinal arteries.

The lack of force in the general circulation is demonstrable by the ease with which the retinal circulation is impeded by slight pressure with the finger upon the eyeball, and such patients are likely to develop the ocular lesions, due to deficient retinal circulations as well as so-called hysterical symptoms.

I have also noticed a rhythmic rise and fall in the force of the retinal circulation, which is of sufficient duration to be easily observed, but I have been unable to obtain a corresponding curve in the pulse tracings.

In some cases I have thought that this was shown by a diminution in the height of the up stroke of the tracing, but the variation, if present, is so slight as to make its demonstration difficult.

I have also observed during the period of low pressure a multitude of minute glistening dots in the retina, which disappear with the return of the normal arterial pressure, a phenomenon which, I think, has been previously noted.

A somewhat similar condition is sometimes seen in patients suffering from organic heart lesions, and these findings are of much importance on account of the frequency with which glaucoma and thrombosis of the retinal vessels develop in such conditions.

It is particularly in those cases which we must class as glaucomatous, but often showing no discoverable elevation of tension that the detection of the impaired heart's action, and its correction are of the utmost importance for the preservation of vision.

In the third group of cases some evidence of organic change in the vascular walls can be made out. The tortuosity to which I have referred as an index of eliminative disturbance is not always seen, but when absent it is safe to assume that it has preceded the condition now present. The curve made by the vessels at the crossings is more pronounced, and the blood-stream of the underlying vessel is somewhat obscured by the wall of the vessel above. The coat can scarcely be said to be visible, but on careful inspection a slight haze can be made out on either side of the red line of the upper vessel. Spasmodic changes in caliber are not the rule, and in well-advanced cases minute hemorrhages, and small whitish areas marking the location of previous hemorrhages which have been absorbed, are sometimes seen. (Fig. 4.)

In the fourth class we will include all cases presenting advanced vascular disease, such as hemorrhagic, albuminuric, and diabetic retinitis, and to this group we will give no extended consideration.

In most instances the diseased condition of the vessel walls is readily discoverable with the ophthalmoscope, and the loss of elasticity in the vascular tunic is shown by the deep depressions at the crossings, and by the obliteration of the blood-stream, by the wall of the superior vessel, which appears in such locations to be bounded by white lines. (Fig. 5.) In some instances the coat is entirely opaque, and the vessel appears as a white band in part of its course.

Many lesions in various combinations are found in this group, but 3 principal types may be mentioned: (1) The hemorrhagic; (2) the degenerative (the classic Bright's retina), and (3) the active type, showing a neuroretinitis or intense papillitis, and occasionally thrombosis of a retinal vessel. (Fig. 6.)

The first prerequisite for the intelligent discussion of any pathologic condition is a clear understanding of the physiologic, the normal and healthy function of the part; but I am obliged to confess at the outset that I am profoundly ignorant of just what takes place in the terminal circulation.

If we clearly understood that biochemic process which we term tissue metabolism, and the exact nature of the control exercised over it by the trophic nervous system, we would naturally be better able to comprehend the derangements of this most important function. Whether the fault is primarily in the nervous system, or whether the disturbance of nutrition is brought about by the presence in the circulating medium of abnormal and irritating elements, the result of improper assimilation, I know not, possibly the causation varies in different cases, but when an autotoxemia is once established, it is self-perpetuating, and unless arrested will sooner or later bring about organic changes in the tissues.

The physical condition which gives rise to the first evidence of disturbed nutrition, visible in the fundus oculi, is, I believe, a high peripheral tension dependent upon or associated with improper elimination, and in the first group of cases which we considered, those showing simple tortuosity of the smaller vessels, the patient's symptoms are those which we would naturally expect in such a condition.

There are no constant general symptoms characteristic of slight nutritive disturbances. In many cases the patients declare that they are in the best health, yet we can usually obtain a history of overwork or worry at some time shortly preceding the examination, or of intemperance in food, over-stimulation, or a neglect of reasonable physical exercise.

If the patient confesses any departure from normal good health, lassitude is complained of, a general lack of energy, and difficulty in mental concentration or a feeling of stress, so-called "nervousness" may be present; patients are unable to relax and rest properly, they will often tell you that they are conscious of holding themselves, even when endeavoring to go to sleep.

Sometimes headaches and vague nervous symptoms are present, such as are common in cases of intestinal indigestion, and constipation is usually found even in patients who are deceived by the normal number of evacuations.

There are as a rule no discoverable physical signs; there may be a slight acceleration of the heart's action, and in some anemic cases a blood murmur, but in most instances symptoms can neither be discovered on examination, nor elicited from the patient.

The one constant abnormality, the condition which I have always found in association with the retinal symptoms which we are considering, is some disturbance in

In practice, however, the elimination of urea will serve as a fairly reliable clinical guide. It is evident that the accuracy of the ocular findings can only be determined when the urinalysis is based upon the known quantity excreted in 24 hours.

It is scarcely necessary to lay stress upon the importance of determining, when making a urinalysis, the quantity of urine voided daily, but I find in practice that this self-evident fact has not impressed itself upon all practitioners, and it is with the greatest difficulty

Fig. 5.

that I can assure myself that the report on any given case is based upon such an examination.

It has frequently happened, in the series of cases under consideration, that the quantity of urea per ounce equaled or exceeded the normal, but that so small a quantity of urine was voided, that the total elimination was far below normal. The statement of the patient, as to the quantity of urine passed, is utterly unreliable.

It is well to bear in mind that a single urinary examination may not reveal the true condition of the patient's excretion, for example:

Miss X., who was referred to me by Dr. B., had suffered some time from constant headache. She had been carefully

Fig. 6.

the elimination. This, in a vast majority of cases, is evidenced on urinary examination by a diminution in the elimination of urea.

As there is a wide physiologic variation in the quantity of urea eliminated by different individuals, bodily habit, occupation, and diet must be taken into consideration, but in many of the cases upon which I have based my conclusions, I have been able by subsequent examinations to determine the normal for the individual, and have thus found that the quantity was diminished at the time of the first examination.

In the very few instances, in which I have been led by the retinal examination to expect a diminution in the excretion of urea, which was not shown by the urinalysis, there has in nearly every instance been such a dislocation of the normal proportion of the urinary elements, that there could be no doubt that the eliminative function was seriously at fault.

That the decrease in the elimination of urea is an important factor in these conditions, I am by no means sure. My knowledge of the significance of the findings of a competent urinalysis leaves much to be desired, and it is possible that an abnormality of some of the less well-known elements in the urine will prove the more reliable indication, and that the diminution in the amount of urea is a coincidence.

examined, but the result was negative as to physical findings, and several careful urinary examinations failed to show any abnormal condition.

On ophthalmoscopic examination, I noted that there was much rigidity of the retinal vessels; degenerative changes in the perimacular region, and spots scattered about the fundus, which suggested previous hemorrhages.

I was convinced that the patient was not in a normal physical state, and so advised her physician, who again examined her carefully, with a perfectly negative result.

At the time I first examined the patient I was not as firmly convinced as I am at present, of the reliability of the retinal findings as an index of the condition of the general economy,

and put this case down as a black eye for my theory, and dismissed the patient.

In the following November the patient reappeared, and I found the condition of the fundus unchanged. Having in the meantime gained confidence by repeated confirmations, I asked her physician to repeat his examination, and at this time the report of the urinary examination was in entire accord with the retinal findings.

"The total 24-hour quantity was 34 ounces; sp. gr. 1020; albumin 5% to 1%; urea 133 grs. in 24 hrs. Fragments of granular casts were found, and some looking waxy, but not absolutely characteristic."

This case will, I think, justify my contention that it is imperative in cases presenting well-marked and persistent ocular indications of eliminative disturbances, that the urinary examination, if at first negative, be repeated at intervals until there can be no doubt of the condition of the patient's elimination.

A like conservatism should be exercised in giving an opinion from an ophthalmoscopic examination, in cases showing but slight evidence of high peripheral tension, for, while in the more advanced cases the retinal condition either remains reasonably constant or progresses, the first evidence of high tension may vary in degree, or at times entirely disappear, and a urinalysis unless made either shortly before or after the retinal examination may prove negative.

This statement is, however, an assumption on my part, for I have never been able to obtain a urinalysis in those cases in which the retinal symptoms have quickly disappeared.

Again, the condition of the fundus, while never entirely returning to normal, may be greatly modified by intercurrent conditions.

I remember one instance, in which I examined a patient for the first time, during her menstrual period, and found very pronounced evidences of high peripheral tension, which a week later was much less marked, the urinary examination being consistent with the later findings.

In the second group of cases the patient will in most instances admit some departure from the normal good health. Headache, mental hebetude, and that train of miseries, which go along with intestinal indigestion, are usually found.

In the cases which present the symptoms of spasmodic contraction of the retinal vessels, of which I have spoken, hemicrania and neuralgias are frequent symptoms; vascular spasm seems, in some patients, to be a habit, which continues from early maturity to middle life, and then disappears as a retinal symptom, with the general neuralgic manifestations occasioned by it.

I believe the amelioration to be due to the hardening of the vessel wall, which prevents the local contraction; and the disappearance of the periodic headache, upon which so many patients congratulate themselves, seems to be an evidence of senility.

Naturally the physical findings vary in these cases, in accordance with the duration of the condition, and in some of the more advanced cases, the heart may show some evidence of the increased load it is obliged to carry.

As a rule, however, no organic lesions are yet found, and the patient's present condition varies all the way from apparent perfect health to so-called nervous prostration, "hysteric" symptoms, and those due to localized circulatory disturbances, are often manifest in this stage.

The urinary findings differ but slightly from those in class one; the low urea is a more constant symptom, and other evidences of imperfect combustion are usually revealed by the urinalysis.

In the third group some discoverable evidences of vascular degeneration are usually present; the radials offer a little more than normal resistance, and there is frequently a discoverable cardiac hypertrophy.

I shall not attempt to catalog the symptoms which may be present in these cases of beginning vascular degeneration.

You all know, in practice, that the widest possible variations exist in these manifestations, in some instances no indications of ill-health are ever experienced by the patient.

The condition is rather one of a rapid progress toward senility, and frequently no sign is given of any departure from the normal health until the final catastrophe affects a permanent cure.

Other patients advance over the same road, perhaps more slowly, but ever hand in hand with the physician, whom they render only less miserable than themselves. Their state is one which has been described as "the habitual enjoyment of ill health," tempered with overwhelming exacerbation of misery, usually excited by the digestive tract.

The urinalysis in this group will as a rule show low urea, low specific gravity, the occasional presence of albumin, hyaline casts, and in the more advanced cases, granular casts are the usual findings.

In the fourth group of cases organic lesions will always be found, if the patients are examined with sufficient care and perseverance, and the retinal findings may be of material assistance in determining the prognosis.

In the cases of retinal hemorrhages, the gravity of the condition will depend largely on the age of the patient, the older the patient the less grave the significance of this symptom.

The type of fundus which I have described as typical of Bright's disease is more apt to be seen in those patients presenting few distressing general symptoms.

I have frequently discovered albuminuric retinitis during the routine examination of the refraction in patients apparently in perfect health, and without impairment of vision. The prognosis in such cases is always bad, the patients as a rule not surviving the appearance of the retinal condition more than 2 or 3 months.

Patients with neuroretinitis and thrombosis are more apt to suffer from cardiac dyspnea and general anasarca.

As the discussion of any of the various conditions included in this group would occupy too much space, I will not consider them further.

There is still another group of cases, which can scarcely be included in any of the foregoing divisions; clinically, they are the patients who most unexpectedly develop well advanced cases of Bright's disease from no known cause, often in early life. When seen before the development of acute symptoms, they show ophthalmoscopically degenerative changes in the vessels, with the marks of previous inflammation, but no indications of an active inflammatory process.

A case referred to me by Dr. F. is an example of this class. The patient, a female of 27, believed herself to be in perfect health; the ophthalmoscopic examination showed some rigidity of the vessels with degenerative spots (old hemorrhage?) scattered about the fundus, there was a large tessellated patch in the left macula, and much tortuosity of the larger vessels, which was apparently due to eyestrain.

Dr. F. reported to me that "the patient had previously suffered from an acute nephritis, and now has a contracted kidney. At present there is no nephritis; arteries small; slight edema under the eyes; some cardiac hypertrophy, and no other general symptoms."

Many such cases, I believe, are the result of a nephritis, following the exanthemata in childhood, and the patients are not conscious of any impairment of health until some time, later in life, from slight exposure, a pregnancy, or improper hygiene, they suddenly develop an acute Bright's disease, which surprises us by its seriousness, and the amount of damage which has apparently preceded the attack.

In the interim, such cases are discoverable by the ophthalmoscope, presenting such a picture as here described.

The majority of patients showing evidences of eliminative disturbances in the retina are between the ages

No.	Age.	Sex.	General Symptoms.	Medical report.	Urinalysis.	Retinal findings.	Remarks.
1	35	F.	Headache and lassitude; looks anemic; while under observation developed choroidal cataract, which almost disappeared under treatment.	Family physician reports 2.5% sugar at time of this examination.	Total quantity = 44 oz.; sp. gr., 1015; albumin, none; sugar, none; urea (total), 297 grs.	Caliber irregularity; terminal tortuosity; arteries and veins relatively large.	This examination made a month later, probably shows a higher urea than was present at the time of first examination, as retinal picture had greatly improved.
2	50	M.	Patient, a physician, thought he had diplopia on arising; has had some headache; symptoms were found later to be due to decentering of strong concave glasses.	Total quantity = 45 oz.; sp. gr., 1019; albumin, none; sugar, none; urea (total), 495 grs.	Terminals unusually straight, but slight rigidity at crossing, not abnormal for age. In left eye slight caliber irregularity (?). Vessels rather small.	This case is given as one in which I suspected a renal lesion, to explain transient paralysis, despite normal retinal findings; urinalysis confirms retinal examination
3	45	F.	Previously treated for conjunctivitis (systemic); noted macular changes at this time. Returned later on account of blurring of vision in left eye; has morning headache; loss of memory; asthenopia; slight dyspnea.	No edema save about eyes; weak heart; radials normal.	Total quantity = 50-60 oz.; sp. gr., 1014-1024; albumin, usually present; sugar, none; urea, normal; casts, hyaline and epithelial.	O. D. Large vessels tortuous and sclerotic; slight rigidity at crossing, not abnormal for age. In left eye slight caliber irregularity (?). Vessels rather small.	
4	10	M.	Came for relief of conjunctival irritation; no symptoms; looks anemic. Mother does not think him perfectly well, but no trouble has ever been discovered.	Total quantity = 30 oz.; albumin, a trace; sugar, none; urea (total), 150 grs.; casts, a few hyaline, probably due to stasis.	Disc outline blurred; choroidal congestion; granular appearance in macular region; vessels tortuous, particularly small vessels; small refractive error does not explain retinal condition.	
5	57	F.	Pain in back of head and mental confusion; has been treated for stiffness of joints.	Family physician reports a weak heart.	Total quantity = 24 oz.; sp. gr., 1020; albumin, absent; sugar, none; urea (total), 120 grs.	Diffuse haziness; arteries small; veins full and dark; light streak absent on veins and arteries; marked venous pulse; vessel walls rigid; some caliber irregularity of larger vessels; some tortuosity of medium sized vessels; fundus indicates general arterial sclerosis, with impaired heart action.	
6	34	M.	No symptoms; has never been ill; comes for asthenopia; after much evasion admits that he has been rejected by a life insurance company.	Family physician reported that pathologist found evidences of renal lesion, but did not give me full report.	No urinalysis.	Around macula and between macula and nerve there are spots which suggest albuminuric retinitis; vessels slightly sclerotic and moderately tortuous.	
7	27	F.	No symptoms; no history of acute illness.	Family physician reports that patient had a previous nephritis; no nephritis at present; has slight edema under eyes; cardiac hypertrophy.	Total quantity = 48 oz.; sp. gr., 1009; albumin, absent; sugar, none; urea (total), 235 grs.; casts, none.	A few white spots (degenerative) scattered over right fundus; larger vessels are tortuous, corkscrew tortuosity, suggests eyestrain; some sclerosis at crossings and a large tessellated patch at macula, suggests old renal lesion with eyestrain. Elimination also possibly defective.	
8	22	F.	Nearly constant headache, and general malaise; hands and feet cold.	Family physician finds urea, 200 grs. a day. Was previously examined for "gross lesion and casts, with negative results."	Slight diffuse edema; arteries light in color; light streak on both veins and arteries broad; large vessels tortuous (asthenopic); terminals crinkly.	
9	20	M.	Has been an athlete, and now has stopped all training and is working hard as a college student; is not feeling well, but has no definite symptoms; heart murmur, probably hemic, present after exertion.	Family physician reported by phone that patient is perfectly sound, and 24-hour specimen is normal. Patient's brother, a physician, informed me later that some six weeks previous to my examination he had a faint turn in the classroom, and at that time he found slight cardiac hypertrophy; irregular rhythm, and soft systolic murmur at base, not organic. States that family physician did not examine 24-hour specimen.	Picture clear in right eye, slight haze in left; thin choroid; large vessels tortuous; slight tortuosity of small vessels; no sclerosis; no retinal lesion; disc margin streaky; asthenopic fundus with slight eliminative disturbance.	
10	35	M.	Had an attack of "serous iritis" two years ago; no discoverable cause; no specific history; uses alcohol moderately; vague rheumatic manifestations; has noticed that urinary secretion has decreased.	Total quantity = 44 oz.; sp. gr., 1019; albumin, none; sugar, none; urea (total), 191 grs.; casts, none. A few pus cells.	No pronounced lesion; slight caliber irregularity; moderate terminal tortuosity; beginning sclerosis at crossings.	
11	18	F.	Is very stout; good color, but circulation poor; some puffing of ankles at times, gets out of breath easily; complains indefinitely of not feeling well.	Family physician reports by phone, low urea; promised report; never received.	Picture clear; pronounced crinkling of terminals; rigidity at crossings; no lesion. On examination a week later showed a marked improvement in retinal condition, while still suggesting high tension, indicates a much less serious condition.	First examination was made during the menstrual period.

No.	Age.	Sex.	General symptoms.	Medical report.	Urinalysis.	Retinal findings.	Remarks.
12	55	M.	No general symptoms.	Total quantity = 22 oz.; sp. gr., 1026; albumin, a decided trace; sugar, none; urea (total), 220 grs. A few hyaline casts.	Large fixed vitreous opacity; spots of exudate between the macula and nerve; tortuosity of vessels.	
13	60	M.	Complaints of blurring in the right eye, which has been noticed for three or four weeks.	Physician reports patient suffering from advanced renal lesion, with cardiac involvement.	Total quantity = 54 oz.; sp. gr., 1021; albumin, some; casts, some; sugar, none.	O. D. Media clear; nerve red and hazy; vessel walls visible at crossings; numerous punctate hemorrhages surrounding the macula; superior branch of retinal artery lost, probably thrombosis. O. S. A few hemorrhages; circulation shows deficiency in force.	
14	21	M.	No symptoms noted by patient.	Total quantity = 26 oz.; sp. gr., 1020; albumin, none; sugar, none; urea (total) 225 grs.	Slight tortuosity of small and medium size vessels; a few white dots in fundus, not asthenopic; slight retinal edema; nerve in left eye blurred; small point of retinitis in macular region.	
15	13	F.	Does not feel well at times; looks anemic; comes for headache, which was relieved by glasses.	Family physician said that she has sugar in urine. No evidence of renal lesion.	Total quantity = 32 oz.; sp. gr., 1014; albumin, none; sugar, none; urea (total), 220 grs.	Retinal haze; arteries small; thin choroid; marked rigidity at crossings; caliber irregularity; terminal tortuosity.	
16	50	M.	Patient states that three months ago family doctor found brain congestion and kidney disease which have now passed away. Patient now complains of pain in the back of his head, and has conjunctivitis of systemic origin.	Total quantity = 56 oz.; sp. gr., 1022; albumin, none; sugar, none; Urea (total), 529.2 grs.	Veins full; terminals very tortuous; caliber irregularity; probably due to changes in vessel walls; some evidences of sclerosis; diffuse haze to fundus.	The history, symptoms, and retinal findings are in agreement, and contradict the results of the urinalysis; this was made by a competent pathologist, and is correct unless the patient was mistaken as to the quantity, no subsequent examination could be obtained.
17	60	F.	Patient reports "kidney trouble" but no convulsions in first confinement; for seven years had swelling of joints with rheumatic pain.	Decreased urea and casts; no details.	Terminal tortuosity; rigidity at crossings; degenerative spots due to previous hemorrhages in both eyes.	
18	30	M.	No general symptoms; some conjunctivitis; has not felt as well as usual.	Total quantity = 21½ oz.; sp. gr., 1020; albumin, none; sugar, none; urea (total), 215 grs. One granular cast.	General retinal haze; perimacular edema; nerve margin blurred; possibly slight neuroretinitis; large movable opacity in vitreous; evidences of old hemorrhages; one small hemorrhage in left eye.	
19	38	M.	About six months ago had acute Bright's disease, which made him blind. At that time albumin and casts were found.	Quantity not given; sp. gr., 1024; albumin, a slight trace; casts, none.	Slight retinal haze; slight tortuosity of medium size vessels; no evidence of sclerosis; fundus suggests previous retinitis, which has made a good recovery.	
20	27	F.	Patient is suffering from hysteric amblyopia; local anesthetics, and other hysteric manifestations.	Total quantity = 51 oz.; sp. gr., 1016; urea (total), 254 grs.	Fundus looks anemic; broad light streak on vessels; circulation lacks vigor; tortuosity of terminals.	
21	13	M.	Patient comes on account of paralysis of accommodation and dilation of pupil, which improved steadily while under observation.	Functional heart murmur; liver slightly enlarged; is anemic.	Total quantity = 37 oz.; sp. gr., 1023; albumin, none; sugar, none; urea (total), 81 grs. Moderate amount of granulo-flocculent material.	Fundus showed no lesion until a month after first visit, when retinal edema, crinkling of vessels, and caliber irregularity appeared.	
22	22	F.	Looks anemic; complains indefinitely of not feeling well; is nervous; hands and feet cold; some headache; has noticed decrease in urinary secretion.	Total quantity = 24 oz.; sp. gr., 1024; urea (total), 240 grs.	Rigidity at crossings; much tortuosity; striations in macular region.	
23	32	M.	Patient overworked; taking no exercise; feels heavy; is growing stouter; history of moderate alcoholism.	Total quantity = 27 oz.; albumin, none; sugar, none; urea (total), 250 grs.	Tortuosity of vessels; no sclerosis; general indications of faulty elimination.	
24	27	M.	Patient has been overworking; complains of feeling tired.	Family physician reports albumin, but no casts.	Right eye shows a patch of exudate beneath the plane of the retinal vessels, and disturbances of retinal pigment; edematous zone surrounds the macula. The left eye, white dots surround the macula.	All retinal symptoms disappeared, leaving simply pigment disturbances at the site of former exudate; patient subsequently passed by life insurance company, showing no renal lesion.
25	60	F.	No general symptoms save indigestion and a weak heart.	Total quantity = 21 oz.; sp. gr., 1023; albumin, a trace; sugar, none; urea (total) 168 grs. A few fragments of granular casts.	Arteries small in proportion to veins; light streak on larger vessels; moderate sclerosis; fine vessels tortuous; retina clear; no marked lesion.	

No.	Age.	Sex.	General symptoms.	Medical report.	Urinalysis.	Retinal findings.	Remarks.
26	20	F.	Constant headache; has been examined by family physician previous to first visit. Urinalysis negative; examined again at my request, six months later — retinal picture remaining unchanged.		Total quantity = 34 oz.; sp. gr., 1020; albumin, decided trace (½%); urea, 238 grs. Some waxy-looking casts.	Rigidity at crossing, perimacular changes; degenerative spots, probably due to old hemorrhage.	
27	51	F.	No general symptoms.		Total quantity = 34 oz.; sp. gr., 1013; albumin, decided trace; urea (total), 238 grs.	Blurred nerve margin; vessels tortuous; veins full; some rigidity at crossing; some degenerative patches in fundus, not recent.	
28		M.	Had nephritis 30 years ago; severe headaches; history of prolonged mental anxiety and overwork.		Total quantity = 60 oz.; sp. gr., 1016; albumin, a trace; sugar, none. Few hyaline casts; albumin not always present.	Vessels tortuous; marked sclerosis of vessels; granular changes in macula; numerous hemorrhages.	Patient is now in extremis with Bright's disease and endocarditis.
29	30	F.	Persistent systemic conjunctivitis; abnormal increase in weight; loss of energy; recurrence of nose and throat inflammation; periodic headaches, so severe as to cause delirium.		Total quantity = 23 oz.; sp. gr., 1033; albumin, none; casts, none; urea (total), 391 grs.	Tortuosity of vessels; caliber irregularity; some rigidity; old patch of choroiditis in left eye.	The urine was so concentrated that upon standing it deposited 8 oz. (¼ of bulk) of mixed urates, making examination impossible.
30	50	F.	No general symptoms.		Total quantity = 48 oz.; sp. gr., 1011; albumin, none; sugar, none; urea (total), 273 grs.	Moderate tortuosity; slight rigidity at crossings.	
31	39	F.	Suffering for several months from episcleritis not improved by local treatment. Indefinite history of lassitude; general depression and headache.	Physician reports cystic degeneration of the cervix uteri and considerable inflammation about the urethra and neck of bladder.	Total quantity = 18½ oz.; sp. gr., 1025; albumin, none; sugar, none; urea (total), 168.3 grs. Two hyaline casts.	Irregularity of caliber; slight visibility of coats; crinkling of terminals.	
32	35	F.	Comes on account of right eye being blurred.		Total quantity = 58 oz.; sp. gr., 1011; albumin, none; sugar, none; urea (total), 168 grs. No casts.	O. D. Thrombosis of retinal vein, hemorrhage, and exudate; no evidence of previous disease in fundus. O. S. Tortuosity of vessels; some rigidity at crossing; no pronounced evidence of disease.	This urinalysis was made after the patient had been under treatment some time; examiner unable to find record of first examination, but says it showed more deficient elimination.
33	30	M.	No general symptoms; has had "bladder trouble," is now better.		Total quantity = 34 oz.; sp. gr., 1021; albumin, none; sugar, none; urea (total), 204 grs.	Marked tortuosity of vessels; coats slightly visible; perimacular changes in left eye.	
34	20	M.	Comes on account of conjunctiva chemosis; no general symptoms; has been told that he had diabetes.		Quantity = 160 oz.; sp. gr., 1008; albumin, 25% (bulk); sugar, none; urea (total), 560 grs.	Neuroretinitis; marked arterial degeneration; numerous hemorrhages in fundus; retinal picture suggests diabetes rather than Bright's disease; probably a mixed case.	The presence of sugar is proved by yeast fungi, seen on microscopic examination; not shown by urinalysis, on account of fermentation.
35	39	F.	No general symptoms save failure of vision in left eye.	Suspicion of specific trouble, confirmed later by finding Hutchinson teeth in youngest child; also family physician says patient had syphilis. Patient died a year later.	Total quantity = 34 oz.; sp. gr., 1013; albumin, a trace; urea (total), 170 grs.	O. D. Large patch of atrophy in macular region suggests previous thrombosis and obliteration of vessels. O. S. Retinitis probably specific; previous inflammation in the right eye prevents accurate estimation of present condition; there is probably serious vascular degeneration and defective elimination.	Case seems to be one of contracted kidney without a very good prognosis.
36	54	F.	No general symptoms.		Total quantity = 48 oz.; sp. gr., 1021; albumin, a decided trace; urea (total), 384 grs. Microscopic examination negative.	Retinal hemorrhages; caliber irregularity of large vessels; retina hazy; slight tortuosity of terminals; marked sclerosis at crossings, with visibility of walls.	
37	50	F.	History of prolonged overwork; insomnia and headache; feeling of great tension; nervous dyspepsia.		Total quantity = 67 oz.; sp. gr., 1017; urea (total), 234 grs.	Moderate amount of tortuosity of vessels; few pigment spots in periphery of retina; vessels normal for age.	
38	54	M.	Has been an athlete, but subject to great business worry, and taking no exercise.	Medical report shows degeneration of vascular system; cardiac hypertrophy with dilation; well marked angula athletica.	Total quantity = 53 oz.; sp. gr., 1016; albumin, none; sugar, none; urea (total), 216 grs.	O. D. Enucleated for glaucoma in 1896; in 1897 slight cupping of disc; tortuosity of terminals; arteries small; very insufficient force in circulation.	
39	37	F.	Comes on account of persistent episcleritis. O. S.		Total quantity = 32 oz.; albumin, none; sugar, none; sp. gr., 1010; urea (total), 195 grs.	Fundus shows evidence of defective elimination; no marked lesion.	
40	62	F.	Patient presents no positive symptoms, but is frail and does not consider herself in good health.		Total quantity = 16 oz.; sp. gr., 1025; albumin, none; casts, none; urea (total), 216 grs. An enormous number of uric acid and oxalate of lime crystals.	Terminal tortuosity; rigidity at crossings; tessellate appearance to macula; numerous yellowish white dots scattered over fundus; small extravasation over disc of left eye. Condition a mixed one of senile choroiditis and vascular disease.	

of 20 and 50; but occasionally children will present this symptom, particularly those ill-nourished children in whom the lack of vigor can be assigned no discoverable cause.

The following case, in a patient of Dr. W.'s, will serve as an illustration of this class.

The patient, a boy of 10, consulted me on account of some conjunctival irritation; the child looked anemic, and the mother stated that he was not perfectly well, but no definite symptoms were present.

The ophthalmoscopic examination showed a blurred nerve margin and much tortuosity of the vessels. A urinary examination made by Dr. W. was as follows:

"The 24-hour quantity, 30 ounces; a trace of albumin was present; urea 1.5%, a few hyaline casts, probably due to stasis." Patient promptly improved under Dr. W.'s treatment.

An inspection of the retinal vessels, is of the greatest value as an aid in determining the general physical conditions, in those cases which we have included in the first and second groups.

If, as it seems to me probable, we can by the aid of the ophthalmoscope detect the first departure from a normal condition in the vascular system, it is possible by dietetic regulations or by medical treatment to prevent the advent of an early senility which is the necessary outcome of this condition.

The retinal symptoms, which are found in classes 1 and 2, I believe to be due to a high peripheral tension which interferes with proper tissue metabolism.

That an increase in the peripheral tension is the condition producing the retinal symptoms, I conclude from the fact that both the retinal picture is improved and the patient's general symptoms relieved, by hygienic regulations and the exhibition of such drugs as tend to decrease the peripheral tension.

The statements made in this paper are, I know, somewhat at variance with our accepted notions as to the possible scope of retinal examinations, and knowing how prone one is to make facts conform to a pet theory, I have honestly endeavored to subject my findings to the most rigid scrutiny. I have appended a few illustrative cases to this paper, tabulated to show my findings at the first examination, and the result of the subsequent examination by the general practitioner or pathologist, and I find that no possible coincidence would explain the agreement.

My deductions are based on some hundred or more cases in which I have obtained a report from the family physician, and in about half of these cases the examination has been made in an entirely satisfactory manner, *i.e.*, a sample from the measured 24-hour specimen has been examined chemically and microscopically by an expert in urinalysis. In this series of cases the retinal findings have been confirmed with the most gratifying exactness.

The field is a wide one, and well worthy of careful cultivation; no doubt experience will enable us to form still more accurate conclusions from a study of the retinal findings.

It seems to me but reasonable that if functional alterations precede organic changes in the circulatory system, they should be discoverable in the eye, where alone in the economy it is possible to inspect a vessel without interfering with its function.

I wish to take this opportunity to express my indebtedness to the members of this club, by whose kind assistance I have been able to obtain most of the material which is here presented.

Mortality in Chicago.—The Bulletin of Chicago's Health Department for the week ended January 30 says: "An old-fashioned winter" is not without its compensations. Notwithstanding that the mean temperature of the month has been 5° below the normal, the deathrate promises to be among the lowest on record. The average January rate since 1893 has been 16.32 per 1,000. For the month just closing it will be about 14. The lowest during the period was 13.69 in January, 1898; the highest, 20.91 in 1893. Last January, although milder than normal, the public health was affected by the "coal famine," and the deathrate was 16.07 per 1,000.

POSTERIOR GASTROENTEROSTOMY, BY A MODIFIED MAUNSELL'S METHOD, WITH AN ENTEROENTEROSTOMY BY THE HARTLEY METHOD.

BY

W. L. WALLACE, M.D.,
of Syracuse, N. Y.

Gastroenterostomy is needed when the stomach cannot empty itself easily through the pyloric opening. The best results are secured by an anastomosis between the posterior wall of the stomach and the upper portion of the jejunum; supplemented, to prevent a "vicious circle," by an anastomosis between the proximal and distal arms of the intestine, a few inches away from the gastroenterostomy. How can a posterior gastroenterostomy by suture, with an enteroenterostomy by Murphy button, be done best in the shortest time, with least danger of infection?

The following technic used in the case of J. C., at the Good Shepherd Hospital, December 10, 1903, illustrates a rapid and satisfactory method of doing this operation.

The aim is to make a posterior gastroenterostomy, working through an opening in the front wall of the stomach. The special instruments needed are 2 hatpins and a flat spring clamp, like an ordinary funis clamp, about 1½ inches by ½ inch:

Steps of Operation.—1. The abdomen was opened and the usual investigation made.

Fig. 1 shows normal relations. Posterior gastroenterostomy will necessitate pushing jejunum (J) through transverse mesocolon (T. M. C.) and uniting it to posterior wall of stomach (S).

2. The transverse colon with great omentum was pulled up and an opening torn through the transverse mesocolon, exposing posterior wall of the stomach.

3. The jejunum, about 8 or 10 inches from its beginning, was picked up, and the funis clamp was placed on its antimesenteric border (Fig. 2) with the long axis of the clamp in the long axis of the gut, pulling the bowel well through the clamp, so as to grasp about 2 inches by ½ inch. A pair of artery forceps was snapped on the funis clamp at (a) to serve as a handle in further manipulations, and to make it impossible for the funis clamp to come open.

4. The clamped bowel was pushed forward through the opening in the mesocolon and against the posterior wall of the stomach, crowding the stomach far out of the abdominal incision, where it appeared as a dome, through the double wall of which the clamp could easily be felt (Fig. 3).

5. A 2-inch vertical incision was made through the anterior wall of the stomach, and the clamped bowel was pushed through this opening, invaginating the posterior wall of the stomach before it (Fig. 4).

6. The posterior wall of the stomach was cut transversely, letting the clamp push through, and the hatpins were passed under the clamp through the posterior wall of the stomach and the intestine, holding their serous surfaces securely together, and allowing them to be drawn far out, invaginated through the opening in the anterior wall of the stomach (Fig. 5).

7. The forceps holding the funis clamp were taken off, the bowel opened by cutting under the funis clamp, and the edges of the intestine and the posterior wall of the stomach were overcast with fine silk, as in Maunsell's operation (Fig. 6).

8. The hatpins were pulled out. Half of a Murphy button was dropped into each arm of the intestine, and then the posterior wall of the stomach, with the intestine anastomosed, was allowed to drop back through the opening in the anterior wall of the stomach, and the opening in the anterior wall of the stomach was then closed.

9. The anastomosis was examined from beneath the transverse mesocolon and the halves of the Murphy button were pushed together, cutting over their cylinders (Hartley method) and the abdomen was closed without a drain (Fig. 7).

Remarks on the Steps of the Operation.—Steps 1 and 2: Same as regular operation, except that a much shorter incision is needed. In this case the stomach was distended with air and water, perhaps left when it was washed out 2 hours earlier. It was emptied instantly and satisfactorily by plunging in a needle connected with a Potain's aspirator. This would be a valuable means of emptying any distended bowel—for instance, in operating for obstruction.

Steps 3, 4 and 5: Through the cut in the anterior wall the inside conditions of the stomach can be examined. It is unnecessary to clamp any arteries, as the posterior wall and the intestine are immediately pushed forward into the opening.

Step 6: When the posterior wall is cut there is no danger of soiling the peritoneum, as all the parts have

Fig. 1.

Fig. 3.

Fig. 2.

Fig. 4.

Fig. 5.

Fig. 6.

Fig. 7.

L, liver; S, stomach; P, pancreas; C, colon; J, jejunum xxxx; G. H. O., gastrohepatic omentum; G. O., great omentum; T. M. C., transverse mesocolon.

been drawn far out in front through the abdominal incision the edges of which are protected by gauze.

Step 7: If thought best, the angle stitches can be passed before the clamp is cut away and the bowel is opened. This will prevent the bowel retracting at the angles where it is not supported by the hatpins.

Steps 8 and 9: The posterior gastroenterostomy is now complete, and the opening is very large, so that no difficulty is experienced in dropping a half of the Murphy button into each arm of the bowel. This insures immediate and absolute drainage of the contents of the stomach into the bowel. In closing the anterior stomach opening I sewed the mucous membrane with a continuous fine silk suture, drawing up the 2-inch opening, making the repair about a half inch long. Over this, the other coats were closed by a continuous Lembert stitch.

Step 9: Hartley's method of using the Murphy button takes a few seconds only, and is very satisfactory.

Remarks.—This method is very rapid and safe. The bowel can be clamped and pushed through the transverse mesocolon, and passed up through both walls of the stomach quicker than the process can be described, and the parts are so securely held that to overcast the edges after the Maunsell method requires a few seconds only.

After-history of Case.—No shock followed the operation. The pulse never went above 90. Nutrient enemata were given at once. Sips of water 15 hours after operation, beef juice 40 hours after operation, and ice cream 48 hours. On December 14 (fourth day), considerable nourishment was given; bowels were open. On December 19, a visitor gave the patient an orange, and he ate it, swallowing the pulp. Six hours later intense abdominal pain began and lasted for 2 hours. Pulse and temperature were normal, and there was no distention or tenderness. On December 21, beginning of twelfth day, the Murphy button was found in the stool. On December 24 the patient left the hospital. Wound healed by first intention. There was no vomiting or abdominal distress, and he was taking plenty of food.

RÖNTGEN RAY TREATMENT OF DISEASE.¹

BY

CLARENCE E. COON, M.D.,

of Syracuse, N. Y.

Instructor in Surgery, College of Medicine, Syracuse University;
Assistant Surgeon, St. Joseph's Hospital, Syracuse, N. Y.

To attempt anything like a detailed description of the many diseases in the treatment of which the röntgen ray is used would require too much space, and therefore I will only call attention, in a brief way, to some of the conditions in which I have found it of value or otherwise.

That the röntgen ray has therapeutic value in some diseases, is admitted by those who are at all familiar with its results. The limitations of its usefulness, time, experience, and conservative work will determine.

Like all new therapeutic agents its value is not appreciated by a large majority of the medical profession, and will not be generally accepted, at least until sufficient time has elapsed to determine whether the symptomatic cures already reported compare favorably or unfavorably with other forms of treatment as regards permanence.

Like all new remedies, too, there is danger from overdoing on the part of those who are experimenting. Extraordinary and impossible claims as to its healing power are made; failure and disappointment will follow, and by indiscriminate and unskilful use of this powerful force, serious injury may result to patient and operator as well as to the progress of röntgen ray therapy.

There are, however, certain diseases in the treatment of which it has been proved that the röntgen ray properly administered possesses curative properties little short of marvelous.

The chief of these is, perhaps, epithelioma; the treat-

¹ Read before the Syracuse Academy of Medicine, October 20, 1903.

ment of this disease is already past the experimental stage, and in the great majority of cases the disease will disappear promptly. I have treated several patients, and have not yet failed to see the infiltration disappear, and the ulceration take on a healthy color and heal, leaving a small, soft, pliable scar.

I saw the first patient in the summer of 1902; the disease was on the chin, and had been present for about 2 years, beginning as a hard pimple, slowly increasing in size, and becoming nodular. For about a year there had been some ulceration, and for several months previous to röntgen ray exposures had not healed, in spite of numerous antiseptic and astringent salves, powders, etc. Seven röntgen ray exposures were given. There was marked improvement from the very first, and the disease disappeared entirely, and at the present time, 1 year and 3 months since treatment was discontinued, there has been no indication of a recurrence.

Other epitheliomas treated since have required more exposures, varying from 11 to 35, but the final result has been the same.

I do not mean to assume that every case of epithelioma is curable by use of röntgen rays, but I have been lucky enough to see cases that responded promptly. Lupus yields nicely to the röntgen ray treatment, but usually requires more time than does the same area of epithelioma; final results, however, entitle this treatment to a leading place among our therapeutic measures.

In acne, röntgen rays possess great therapeutic value.

One patient was a lady, who for 15 years had had the shiny red nose, with an area of bright erythema surrounding, many papules and pustules under eyes, over malar regions, and on lips and chin. She had had various forms of treatment, diet, etc. The condition would improve for a time, but never disappear or remain quiet for any length of time. She was given 17 exposures during March, April, and May, 1903; improvement was noticed from the first, and continued until the only sign of trouble left was a slight redness of the tip of the nose. During röntgen ray exposures the patient had no other form of treatment, and there was no restriction of diet. There is not the slightest evidence of recurrence as yet.

In tuberculous inflammation of the lymphatic glands, previous to caseation and suppuration, results have exceeded my expectation.

One patient, who was treated in May and June this year, was a girl of 9, who had undergone a radical operation for cervical adenitis about a year previous. At beginning of röntgen ray treatment there were several palpable glands, two just in front and below the angle of the jaw, the larger one about $\frac{3}{4}$ in. in diameter, the smaller about half that size. Along the posterior margin of the sternocleidomastoid was a chain of glands which felt like a string of beads; several scattering small glands could be felt. There were 17 exposures given. The glands disappeared entirely, so far as could be determined by palpation. There is no evidence as yet of returning trouble.

Old sinuses with pouting granulations, which sometimes occur after an operation for some tuberculous disease, or more often when a suppurating gland has been opened, and which show little or no evidence of healing, will often respond very promptly to röntgen ray stimulation.

Tuberculous disease of the joints improves very slowly. A child aged $4\frac{1}{2}$ has been treated nearly every day since June for extensive involvement of the knee. The patient has improved, but is still under treatment.

There are other diseases including eczema and psoriasis, in which many cures are reported by other observers, but about which I cannot speak from experience.

With the deepseated carcinomas results have not been so encouraging. In this class of cases the only benefit to the patient that one can feel reasonably sure of obtaining is the relief from pain, or control of hemorrhage when present. All observers agree that the röntgen ray is analgesic.

This is very strikingly illustrated in the following cases:

The entire right breast and axilla was one mass of carcinoma, and for several months the patient had had a great amount of pain, and for 6 weeks previous to beginning röntgen ray treatment, it had been necessary to take an opiate as often

as every 2 hours to relieve the excruciating pain. She was given an exposure of 15 minutes. When she appeared for another treatment on the second day she said she had slept well for 2 nights and had been free from pain. She remained free from pain during the 3 months she was under observation.

I have noticed also that most patients who are exposed to the röntgen ray seem to improve in their general condition, they appear brighter, more cheerful and less nervous.

A lady of 68 had carcinoma of the breast. Previous to operation she received 11 exposures. Following operation, healing was unusually prompt and raying was resumed, 20 exposures being given. During the time from the first to the final exposure, and this includes the time for operation and recovery, she was a very cheerful patient. About 2 weeks after this she began to be very nervous and irritable and quite despondent, and not at all like the cheerful, hopeful patient she had been.

Of course this may have been due to other causes in this particular case, but with a majority of patients after receiving a few rayings, it is a common occurrence for them to say that they feel better than they have for a long time.

In the treatment of sarcoma my observation has been limited to 2 cases—one an osteosarcoma of the femur; the other of the jaw. In neither case was there any diminution of the size of the tumor. There are cures reported.

If the value of the röntgen ray should be limited to what has already been proved, its effect upon skin lesions, it would occupy a very important place therapeutically; but the fact that some of the deepseated malignant growths disappear, as reported by other men, leads us to hope in the future more can be successfully treated.

That radiotherapy will supplant surgery in the treatment of malignant disease, does not seem at all probable, rather will it help the surgeon to prevent some of the recurrences following an operation.

In those cases in which the disease is too far advanced for operative interference, this treatment should certainly be given: for its action in relief of pain, as a hemostatic, as a tonic to the patient, and with a little hope for cure of the primary disease.

In the treatment of epitheliomas it gives a method which has advantages over excision or use of caustics. 1. The resulting scar is small, soft, and pliable, and the best possible cosmetic effect is thereby produced. 2. It is painless. 3. It allows the patient to continue at his usual occupation during treatment. The chief disadvantage of this treatment is the length of time necessary to complete the cure.

In the treatment of lupus, eczema, psoriasis, and other chronic nonmalignant skin affections, it offers hope of relief in cases which resist all other forms of treatment. In tuberculous disease, including pulmonary tuberculosis, good results have been attained, and further study and experience will determine just how much value is to be given this form of treatment. If we accept the reports of the many röntgen ray therapists, we must believe that radiotherapy is indicated and advisable in epitheliomas, all inoperable malignant growths, as an after-treatment in operations for removal of malignant disease, in the earlier stages of tuberculous adenitis, and in all forms of chronic skin disease which do not yield readily to ordinary treatment.

In the use of the röntgen ray as a therapeutic measure, there are some things to be considered other than the control and running of the apparatus. The power of this light is not yet fully understood. Enough is known, however, to recognize some of its dangers. Each individual patient must be studied to determine the length and frequency of exposure necessary to obtain the best results without producing serious burns. There is also danger for the operator in too frequent or prolonged use of the fluoroscope or too frequently placing some part of the body, usually the hands and forearms, in the area of light.

In considering the mass of evidence which is rapidly accumulating, one cannot help but believe that in the röntgen ray we have an extremely valuable therapeutic agent, and when the limitations of its usefulness shall have been determined, it will take its place as a remedy par excellence in some diseases.

HOUR-GLASS CONTRACTION OF THE UTERUS.

BY

CHARLES F. BEESON, PH.G., M.D.,

of Roswell, N. M.

Ex-House Physician, Cincinnati Hospital; Late Surgeon Colorado Fuel and Iron Company.

An interesting case which occurred in my practice has convinced me that the pregnant uterus can and does, under certain circumstances, contract in such a manner as to defeat the very object which nature intends uterine contractions to accomplish. In nearly all other physiologic phenomena of the body, perversions of action do take place, then why not in the action of the pregnant uterus at term, which is the greatest physiologic phenomenon of all. We see all grades of uterine inertia and dystocias from many causes, and their limitation is in all probability due to the fact that the etiology of such irregular actions has been suspected, and such causes avoided by our best teachers.

The following case came under my observation in a Mexican hut some months ago while employed by the Colorado Fuel and Iron Company:

CASE.—Mexican, aged 16, primipara. The patient, who was of large build and well nourished, had been in labor 27 hours, according to the Mexican midwife whom I found in attendance. The first thing that attracted my attention was the peculiar shape of the abdominal tumor (Fig. 1). The uterus was in a state of tonic contraction with clonic exacerbations occurring about every 15 minutes. The pains were not strong and were apparently accomplishing nothing. Fetal heart 144, was heard best in the left lower quadrant. Vaginal examination revealed the os dilated to the size of a silver quarter, cervix thin and tense, membranes intact, head presenting, L. O. A. position. The bladder and rectum were empty, pelvic measurements practically normal. Woman in good condition.

I left her with instructions that if the baby was not born in 8 hours to let me know. In due time I was called again, and found the condition practically unchanged, except that the woman was becoming exhausted. Temperature normal, pulse 120. Pains were a little stronger if anything; between pains the presenting part was movable above the brim and receded considerably after each pain as though a short cord was interfering with the progress.

I decided to put the woman under chloroform and introduce my hand into the uterine cavity to find out, if possible, what the trouble was, as the pains seemed sufficiently strong, and yet the head would not engage. I thought forceps were counterindicated, at least until a thorough investigation had been made. I inserted my hand into the os which I dilated, then rupturing the membranes, passed my hand over the head of the child and onto its neck, and to my surprise found an obstruction between which and the child's chest I could not insinuate my fingers try hard as I could. I passed my hand around to the right and found a constriction extending completely around the inside of the uterus and striking the child at the shoulders. The body of the child was too large to pass forward through the constriction and the head was too large to be pushed back through it. I could easily turn the child on its long axis and push its head up against the constriction; dilation of the constriction by the hand seemed impossible. Version could not be performed, and forceps were certainly counterindicated. I requested the anesthetist to push the chloroform to the third stage, and I then applied the forceps; a 7-pound child was very easily delivered, the constriction had disappeared completely, the uterus assumed its normal condition, and the placenta came away normally in due time; a slight postpartum hemorrhage followed, but by persistent kneading of the uterus and hypodermic injections of ergotol uterine contractions were maintained until sufficient clotting of the uterine sinuses prevented a fatal issue. The child had to be resuscitated, but soon revived and was in a short time in good condition. Mother and child did well from that time on. By measurement upon my hand the contraction ring was about 5 inches from the rim of the external os (Fig. 2).

In attempting to review the literature upon this subject I soon found that I had here a very rare condition; reports of cases in which a contraction ring had grasped

the child in such a manner as to prevent its escape were very scarce and all of ancient origin, some modern textbooks not even alluding to it.

Cases in which the placenta became encysted in the uterine cavity by a contraction ring have been reported recently. Older writers seem to have known of a condition similar to the one I have here reported, but no case of recent origin has been reported to my knowledge.

Wm. H. Taylor* has furnished me with the following translation from Veit in the *Monatsschrift für Geburtshilfe und Gynäkologie*, 1900:

All observation must admit the possibility of the contraction of Bandl's ring, but it is not proved that the condition develops without simultaneous contraction of the body of the uterus. From my own experience I am not able to speak of cases in which the head lies in the lower uterine segment and extraction by the forceps is prevented by the contraction ring. Of cases in which the uterus is spasmodically contracted, retaining the child in the cavity of the uterus, I know nothing. . . . There may be mistaken for this, cases in which with insufficient uterine action the membranes rupture early and the internal os does not dilate, consequently the upper part of the uterus remains soft, but the internal os may be rigid and prevent the entrance of the hand. In such a case it is the internal os and not the contraction ring with which we have to do.

He quotes Williams, of Johns Hopkins Hospital, who says:

French observers believe that, while the portions above and below it remain flaccid, Bandl's ring can undergo isolated contractions and thereby so strongly compress the neck or some other portion of the child as to interfere seriously with its delivery. It is probable the condition is really due to more or less rigidity of the internal os while the cervical canal below it has undergone satisfactory dilation.

Then again, Veit, who says:

For years I have specially observed every separation of the placenta and every exploration of the uterus and I have never felt an isolated contraction of the contraction ring.

Playfair says:

An important cause of postpartum hemorrhage is partial and irregular contractions of the uterus. Part of the muscular tissue is firmly contracted while another portion is relaxed. One peculiar variety which has been dwelt upon by writers is the so-called hour-glass contraction. This in reality seems to depend upon spasmodic contraction of the internal os, by means of which the placenta becomes enclosed in the upper portion of the uterus which is relaxed. On introducing the hand, it first passes through the lax cervical canal until it comes to the closed internal os which has generally been supposed to be a circular contraction of a portion of the body of the uterus. These irregular contractions are not so common as older writers supposed. When they do occur, I believe them almost invariably to depend on defective management of the third stage of labor.

Hirst thinks it a contraction ring due to obstruction to labor from a rigid cervix. He admits the possibility of the so-called hour-glass contraction as it is usually interpreted, but says he has always been sceptical as to its probability.

Hasmer² has drawn attention to a form of dystocia which he calls antepartum hour-glass contraction and which he believes to depend on a contraction of the uterus at the internal os.

Blundell refers to it in his work (1840) under title of "Circular Contraction of the Middle of the Womb."

Harris doubts its limitation to the internal os and

* Obstetrician to the Cincinnati Hospital.

Fig. 1.—(Diagrammatic.)

terms it "falciform contraction of the uterus." (Text-book 1897.)

Lusk refers to hour-glass contraction of the uterus as occurring in the third stage. He thought it due to administration of ergot.

S. S. Turner³ reports a case of hour-glass contraction of the uterus in the third stage of labor interfering with the delivery of the placenta, but he does not give any idea as to where the contraction took place.

Contri⁴ gives a similar case to Turner's, but without alluding to the probable site of the constriction. It is readily seen from the literature obtainable that there

Fig. 2.—A, uterine wall; B, contraction ring at internal os; C, distended cervical canal; D, external os. (Diagrammatic).

is considerable doubt among our best observers that an isolated contraction above the internal os, interfering with labor, ever takes place.

As Taylor says, it is not a question as to whether a contraction does take place, but where does it occur?

Whatever its site in the cases recorded by the older writers, difficulties of the most formidable kinds arose from this cause. The pelvis were properly shaped, and the presentation normal, yet out of 7 labors 4 ended fatally, 2 before delivery. The contraction seems to have grasped the fetus with such force as to have rendered extraction either by forceps or turning impossible.⁵

In looking over the anatomy of the pregnant uterus late in gestation we find that 3 layers of muscle fibers having different actions are distinguished: External (longitudinal), middle (oblique), and internal (circular).

The external layer is continuous with the muscle fibers of the round ligaments and tubes and is mainly longitudinal in arrangement. By their action the diameters of the upper uterine segment are shortened, thereby pressing the uterine contents toward the lower uterine segment.

The middle layer is composed of bundles which pass from their peritoneal attachment obliquely downward and inward to be attached to the submucous tissue, the oblique arrangement being less marked above Bandl's ring, but below this point they are more pronounced, in fact, they constitute the bulk of the uterine wall between Bandl's ring and the internal os. When acting, these fibers aid in dilating the lower uterine segment, and assist the action of the longitudinal fibers, pulling the lower uterine segment up over the presenting part.

The internal layer is thin and poorly developed, except around the orifices of the uterus. Its arrangement is chiefly circular, and is most strongly developed at the openings of the tubes and at the internal os. By

its action, it retains the smaller caliber of the lower uterine segment, checks the action of the oblique fibers, and thereby aids in preventing a precipitate labor and consequent rupture of the lower uterine segment. (Fig. 3.)

By actual observation we know that after prolonged action muscle fibers become exhausted, and when antagonizing another set of fibers their exhaustion will allow of apparent overaction of the antagonist; as is seen in obstructed labors when the lower uterine segment becomes thinned and its fibers exhausted a rupture may take place; so if after prolonged action the oblique fibers should become exhausted before the circular fibers are paralyzed, I believe we would have overaction of the circular fibers, or at least they would have no strong antagonist and would consequently contract, forming a ring such as we have in the case cited.

The exact location, therefore, of this contraction ring would be where the circular and oblique fibers meet, which is in the region of the internal os.

The fact that the oblique arrangement of the middle coat is more pronounced below Bandl's ring (Fig. 3) and that its origin is in the peritoneum at and above that ring, with its insertion in the lower uterine segment, readily shows the cause of Bandl's contraction ring when these fibers are pulling against an obstruction below, causing a recession at their origin. In the case cited Bandl's ring was not present as is seen in obstructed labors, but instead the uterus was apparently standing on end, caused by a contraction ring more pronounced and situated much lower in the pelvis than Bandl's contraction ring is usually situated. This would seem to make it plain that Bandl's ring had ceased to exist when the oblique fibers became exhausted. That would certainly occur were this theory correct.

That the condition described, maintained in my case is almost certain, and that a similar condition was present in the cases of the older writers and in those cases of encysted placenta is probable. That a recession at the origin of the oblique fibers, constituting Bandl's ring, could interfere seriously with the delivery of the child does not seem probable from an anatomic standpoint (Fig. 4), although it is certainly possible.

The causes of this condition are probably many, different ones acting in different cases; mismanagement, as we see it now, is the prime factor.

Of predisposing causes we might mention primiparous rigid cervix, uterine inertia, and any condition interfering with the serous infiltration of muscular structure of the lower uterine segment, which might be brought about by undue manipulations in the early stage, tight bands, etc.

Of the exciting causes we might quote Playfair, who says: "The most frequent cause of the so-called hour-glass contraction is over-anxiety to remove the placenta;

Fig. 3.—Section of wall of pregnant uterus. (Holmeir and Hirst's textbook). A, Bandl's retraction ring; B, origin of oblique fibers; C, oblique fibers; D, circular fibers; E, internal os; F, external os; G, insertion oblique fibers.

the cord is frequently pulled upon, while no attempt is made to excite the fundus to proper action."

Johnstone says: "Ergot given before the expulsion of the placenta."

In the case reported in this paper I have no knowledge of what was done before I saw the patient, and the condition was probably present when I was first called, at least the peculiar shape of the abdomen first attracted my attention. The Mexican midwife had given nothing, and I have found that they know nothing of ergot or any drug that has positive action on the uterine muscle. The only thing that I have ever known them to do is to tie a tight band around the body above the fundus uteri and put the woman on her knees, slipping the band downward as the tumor descends into the pelvis, just as a housewife would squeeze the pudding out of a bag. This is always done by them in difficult labors, and why it should cause the condition in this case and not in others I am not prepared to say, possibly a rigid cervix and the band together brought about an exhaustion of the oblique fibers before the circular fibers were completely conquered, the latter being able to stretch over a small head without becoming paralyzed.

The jamming of the uterus into the pelvic cavity by the band may have interfered with the serous infiltra-

made by inserting the hand into the uterus and feeling the constriction.

The prognosis is not encouraging. If the forceps were applied, a pull upon the head of the child would certainly result seriously. As to whether the constriction would disappear after a time I am not prepared to say, but in the case cited it was present about 8 hours, and how long before I saw the patient I do not know, but giving 17 hours for a normal labor, we could add 10 hours to the 8, making 18 hours for the constriction.

Of 7 cases reported by old writers, 4 proved fatal. It seems to me that with modern treatment, a fair show for both mother and child may be expected.

The treatment will depend upon a correct diagnosis. Management of labor cases as laid down by our modern obstetricians will lessen the liability to such an accident.

Ergot should not be given until the placenta comes away. Undue manipulation, tight bands, etc. in the first stage should not be used.

To treat the condition, chloral may be tried; atropin injected at the site of the constriction, has been recommended. Manual dilation should be attempted. Chloroform given to profound narcosis caused the contraction ring to disappear in my case.

Version might be accomplished, and finally cesarean section, as reported in a case by Dr. T. A. Foster, of Portland, Maine, if other means fail.

I desire to thank Dr. Wm. H. Taylor, of Cincinnati, Ohio, and Dr. Barton Cooke Hirst, of Philadelphia, for valuable suggestions.

The Biggest Heart in the World.—An exchange says the biggest heart in the world is soon to be subjected to dissection. It is owned by Professor Burt G. Wilder, of the department of physiology of Cornell University, and once thumped inside of Jumbo, the famous elephant that was killed by a locomotive. It is now preserved in a barrel at Cornell. Jumbo's heart is 98 times as large as the average human organ. It now weighs 364 pounds after having soaked several years in alcohol. A human heart, which weighs a little more than a pound, soaked in alcohol for the same length of time, weighs 10 ounces. The human heart is less than 6 inches long. Jumbo's is 28 inches long and 24 inches wide. The ordinary heart could be contained in the main artery of Jumbo's heart. The walls of the artery are five-eighths inch thick, while the walls of the ventricle are 3 inches thick.

Increase of Crimes During 1903.—The Chicago Tribune, having collected data from various sources during the year 1903, gives its compilation as follows: "There were 8,976 crimes resulting in death by various forms of violence in 1903, a small increase over 1902, when there were 8,834. One of the most significant features of this record is the fact that 406 of these murders were committed by thugs and hold-up men, being nearly twice as many as were committed last year, and showing proportionately the increase of lawlessness. There were 8,597 cases of suicide in 1903. The following figures show the steady increase of self-murder: In 1899, 5,340; in 1900, 6,755; in 1901, 7,245; in 1902, 8,291; in 1903, 8,597. As has been the case during the last 3 or 4 years, poisoning and shooting have been the principal methods, the two numbering 7,677 out of 8,597. The ease with which poison may be obtained accounts for 4,050 of these cases. The total number of legal executions in 1903 shows a falling off compared with last year, being 123, as against 144 in 1902, 188 in 1901, and 110 in 1900. There were 77 hanged in the South and 46 in the North, and of these 63 were white and 60 colored. The largest number of hangings was 11 each in Missouri, New York, and Alabama; 10 in Virginia, 9 in Georgia, and 8 in Pennsylvania. Lynchings numbered 104, as compared with 96 in 1902. Notwithstanding this comparatively slight increase, an examination of the reports for several years back shows that there were many less lynchings in the decade just closed than in the preceding decade. The total for 1903 includes 92 in the South and 12 in the North; 86 negroes, 17 whites, and 1 Chinaman; 102 men, and 2 women. The 2 principal alleged crimes were murder, 47 cases; and criminal assault, 20. Arkansas, Georgia, Louisiana, and Mississippi led the list, with 11, 12, 14, and 18, respectively. Alabama had only 2 cases, and there were 2 Southern States, Maryland and Virginia, which had none."

Fig. 4.—A, external os; B, internal os; C, oblique fibers; D, Bandl's retraction ring. (Diagrammatic).

tion of the lymph spaces of the lower uterine segment which would in all probability cause an abnormal action in these parts.

The cervix had undergone sufficient dilation to admit the small head of the child, the internal os had evidently been drawn backward over the presenting part, lengthening the cervix to about 5 inches, and then at the last moment we might say the oblique fibers failed in their duty, allowing the circular fibers to close down upon the child's neck.

Why the condition is not reported oftener in these mismanaged cases may be that while it does occur, it is not recognized, and the oblique fibers, after a season of rest, take on renewed energy and complete the labor as in other forms of uterine inertia.

The symptoms of this condition would be those of uterine inertia, plus the peculiar shape of the abdomen and an unusual recession of the presenting part after each pain.

The condition should be suspected by the peculiar prominence of the abdominal tumor, the depression just back of the symphysis pubis, and by the absence of other causes of dystocia. The diagnosis could be positively

1.—Influence of Trauma in Production of Movable Kidney.—M. L. Harris, from a careful study of the subject, reaches the following conclusions: Movable kidney occurs in women with a particular body form (distinct relative contraction in the capacity of the middle zone), and practically all women with this body form have movable kidney of greater or less degree. Movable kidney is not produced immediately, but requires time for its development. While it is possible to injure, crush or suddenly displace by violence a normally fixed kidney, such displacement is always accompanied by laceration of the perirenal tissues, which is manifested by distinct local and general symptoms. Severe injuries involving the kidney or perirenal tissues are seldom or never followed by movable kidneys, and the latter is never the result of a single trauma. [H.M.]

2,3.—See *American Medicine*, Vol. V, No. 24, p. 945.

5.—Influence of Resection of the Cervical Sympathetic Ganglions in Glaucoma.—W. H. Wilder presents a detailed report of 7 cases of sympathectomy still under observation in his own practice. In all of the specimens there was increased pigmentation of the ganglion cells. In 2, mast cells were seen. In 3, the cells were not round but irregular. In 1, cells slightly vacuolated were seen. In 2, they showed eccentric nuclei and marked vascularity was present. He also gives abbreviated records of 68 operations done on 54 cases by others. Of 38 operations for simple glaucoma 14 gave no improvement whatsoever, 5 improved for 15 days to 8 months, but had recurrent attacks necessitating iridectomy or caused loss of the eye; 15 improved from 2 months to 2 years. Of these, 3 were stationary, 1 died, 6 remained unimproved after iridectomy, but improved after sympathectomy. Of the 16 operations for chronic inflammatory glaucoma 6 showed no improvement, 3 improved for 2 or 3 months, 4 improved as long as under observation, one 5 months, one 18 months, one 1 year, one 3 years. Of the 4 operations for subacute glaucoma one was cured at the end of 2½ years, 2 remained well after 15 months, 1 remained improved after observation of 4 months. Of the 3 operations for acute glaucoma 1 recovered, 1 improved, 1 was preventive. Of 4 operations for absolute glaucoma, 1 improved as to pain, in 3 there was no improvement or change. Of 2 operations for hemorrhagic glaucoma 1 improved as to pain and 1 as to vision. One operation for buphthalmos had no effect. After these 68 operations miosis is mentioned 40 times, ptosis 36, conjunctival congestion 19, congestion of the face on the side operated on 6 times, neuralgia and hyperesthesia 6, anesthesia 2, hoarseness or aphonia 8 times, dysphonia once, dysphagia 5 times, and in 1 case the patient had mild hallucinations. [H.M.]

6.—New Aspects of Yellow Fever Etiology.—C. J. Finlay, by analogy with the life cycle of the malarial parasite, suggests the probable character of the evolutions which the yellow fever germ undergoes in the body of the host. If penetration into the body of the nonimmune is intended for the accomplishment of sexual reproduction, and if the analogy between it and the malarial parasite holds good, with the difference only that the latter accomplishes this act in the anopheles mosquito while the yellow fever germ does so in the human host, the following important inferences may be drawn: The minimum number

of days (estimated at 10 or 12) which must elapse after the stegomyia has bitten a yellow fever patient before the infected insect is able to inoculate the disease through its bites, must represent a series of transformations in the body of the contaminated mosquito, including the introduction of young sporozoites sucked up with the blood of the patient, the growth of these to adult age, formation of schizonts and merozoites and gametes. While in the body of the nonimmune, counting from the moment of his inoculation by the infected stegomyia, the following stages are likely to take place during the period of incubation: Localization of gametes in appropriate sites, fecundation of the macrogametes by the microgametes, formation of the oocyst in appropriate cells (endothelial), discharge of free sporozoites of yellow fever into the circulating blood, development of the toxemic symptoms characteristic of the invasion of yellow fever. [H.M.]

7.—Present Status of the Uric Acid Question.—W. Baumgarten summarizes our present knowledge as follows: The source of uric acid in mammals lies in the nucleins and their decomposition products, the purin bases. The uric acid eliminated in the urine arises partly from the breaking down of cell nuclei (the endogenous uric acid), and partly from the food (exogenous). The amount of endogenous acid is the minimum which the individual normally excretes; it does not change in quantity, though it varies with individuals; it is influenced by the mode of life, but in no way by the quantity or character of the constituents of the food, which do not belong to the group of nucleins and purin bases. The exogenous acid depends in amount on the quantity of certain purin bases in the food. Of the free purin bases only the oxypurins, hypoxanthin, and xanthin, increase the uric acid elimination; of the bound bases both oxypurins and aminopurins increase the uric acid; the methylated purin bases do not affect the uric acid elimination but increase the purin bases in the urine. Of the oxypurins, both bound and free, half is excreted in man as uric acid; of the bound aminopurins some appear half, some a fourth as uric acid. [H.M.]

8.—Tuberculous Joints.—D. C. Peyton advises the use of tuberculin in doubtful cases, and radical treatment so soon as the diagnosis is made. It may be safe to rely on rest, fixation and fresh air for 10 days or 2 weeks, provided early diagnosis has been made, but the writer has had eminently satisfactory results from early and free opening and drainage, and thorough irrigation of the joint with a hot, normal saline solution, repeating this for a week or 10 days. This is especially commended in patients under 18, for by more radical operations we may destroy the epiphyses, with consequent arrest of development. In advanced states of the disease in either adult or child, arthrectomy or excision is imperatively demanded. [H.M.]

9.—Diphtheria of the Nose.—W. Scheppgregell finds the constitutional disturbances frequently so mild they attract little attention, the physician being appealed to on account of obstruction or epistaxis. The early symptoms resemble those of coryza. The mucous membrane is covered with a light-gray pseudomembrane. This sometimes is followed by cicatricial tissue or synechiæ. The affection is ordinarily so mild ordinary methods of isolation are difficult to enforce. One negative bacteriologic examination is not decisive. The prognosis is good. The writer's treatment is simply syringing with 25% peroxid of hydrogen, followed by free douching with normal saline solution. From those cases which have come under his observation, no second case has developed. [H.M.]

Medical Record.

February 13, 1904. [Vol. 65, No. 7.]

1. Some Personal Observations and Experience of the Schott Treatment of Heart Diseases. WILLIAM W. BALDWIN.
2. Contribution to the Study of Spondyloze Rhizomelique, with Report of Three Cases. ALFRED GORDON.
3. The Antiseptic Treatment of Pneumonia in Infants and Children. S. HENRY DESSAU.
4. Hernia in Young Children. W. B. DE GARMO.
5. Radiotherapy, with Report of Cases. D. C. DENNETT.

1.—The Schott Treatment.—W. W. Baldwin thinks this method might be employed successfully by every general

practitioner. Its curative effects are greater and more permanent than those from drugs and rest. The immediate effects of the baths are not so brilliant as those following the exercises, but last longer. The physician should be present at both bath and exercises when not acquainted with the patient's limitations. Contraindications to the baths are advanced arteriosclerosis, advanced nephritis with high tension, aneurysm, grave cases of organic heart disease too advanced to react, great anemia, and emaciation. Bronchial asthma and bronchitis demand caution to prevent chilling. Thorne has used the baths with advantage even when pulmonary tuberculosis complicates the heart disease. The author describes the 5 kinds of baths used. While the artificial baths give excellent results, he prefers an additional course at Nauheim when possible. Digestive disturbances should receive appropriate treatment early. He discusses the technic of the baths and exercises, and reports several cases. [H.M.]

2.—Spondyloze Rhizomélique.—A. Gordon presents several cases with illustrations. There are multiple conditions producing limitation of movement of the spinal column including tabes, syringomyelia, spinal muscular atrophy, interstitial hypertrophic neuritis, myositis, hypertrophic cervical pachymeningitis, chronic deformant rheumatism and gout. These may give more or less a picture of both Bechterew's and Marie-Strümpell's types. It is doubtful if the disease is a pathologic entity. It should not be considered an expression of rheumatism because the patient gives a history of this disease earlier in life. A great many cases present symptoms of cord involvement. Spondylosis is only a symptom of a more complicated disease, the etiologic factor of which is not at all elucidated. [H.M.]

3.—Antiseptic Treatment of Pneumonia in Infants and Children.—S. H. Dessau recommends carbolic acid in both lobar and bronchopneumonia, 1 dr. of a 2% solution being given every 2 hours with creasote and eucalyptus evaporations in the room. The carbolic acid promotes sweating and the crisis is converted into a more gradual termination. Albuminuria is not a contraindication. It aids in maintaining normal digestion. [H.M.]

4.—Hernia in Young Children.—W. B. De Garmo states that the principal predisposing cause of hernia in young children is defective development. Often the pouch of peritoneum which descends with the testicle is not cut off from the abdominal cavity, a patent canal remains which invites the occurrence of hernia. The second most common cause of this condition in early life, he believes, is constipation; gastrointestinal disturbance producing distention of the intestines by gas is also given as a cause; again, whoopingcough, bronchitis, crying, and tight abdominal bands predispose. The forms of hernia met with in young children are inguinal, umbilical, ventral, and femoral in the order named. The popular belief that infants outgrow hernia is erroneous and often leads to neglect fraught with danger. A truss should be applied so soon as a hernia is discovered, and if this is continued surgery will seldom be needed in early infancy. In an operative experience of 1,064 cases of hernia by the author only 4 were upon infants under a year old, and these were cases of strangulation, but 179 were in children under 14 years of age, and among these there was no death. He employs the Bassini method, though using kangaroo tendon instead of silk. He gives the following indications for operating upon hernia in early life: 1. Strangulated hernia—immediate operation. 2. All cases not controlled by truss. 3. Occasional protrusion with threatened strangulation. 4. When truss-wearing causes pain. 5. On children that cannot be brought regularly for attention. 6. In all cases of femoral hernias. 7. On all children over 7 years of age. [A.B.C.]

5.—Radiotherapy.—D. C. Dennett states that radiotherapy is no longer confined to the treatment of disease by the röntgen rays alone, but is likewise applied to treatment by means of radium, Becquerel rays, etc. He reports a series of 12 cases selected from those whom he has treated by means of the röntgen rays; among these were 6 cases of eczema, all of which were entirely cured; 1 case of psoriasis, one each of epithelioma of the lip, of the arm, and of the face; one of rodent ulcer. All were cured. A case of cancer of the stomach was apparently in no way benefited by this method of treatment. The author

states that trachoma yields readily to treatment by means of röntgen rays. Following the report of his cases is a discussion upon the best means of applying the rays for curative purposes, together with the mechanism of the apparatus used. [A.B.C.]

4. The Sanitary Needs of Panama. M. L. MADURO.
5. A Suggestion for the Rapid Calculation of Percentage Milk Mixtures: With Description of a Mechanical Device for the Instantaneous Calculation of Such Formulas. THOMPSON S. WESTCOTT.

2.—Day and Night Urine.—C. W. Edmunds reviews the literature of the subject and discusses the relative proportion of urine secreted during the day and the night in health, and in certain pathologic conditions. Tables are given showing the results of research in 56 cases, including miscellaneous, acute, and renal and cardiac diseases. He confirms earlier writings as to the nocturnal polyuria occurring in renal and cardiac disease, and points out the value of this fact as a diagnostic sign, especially in cardiac disease. He adds the possibility of tracing the course of a nephritis or of a cardiac disease by observing the changes in the relative amounts of day and night urine for short periods of time. When drugs which cause diuresis are administered during the day, they tend to restore the normal ratio. [C.A.O.]

3.—Infantile Bronchitis.—The different forms of this disease and their physical signs and symptoms are taken up by E. M. Sill. If seen in the first stage, when nothing can be heard but harsh breathing and a cough, the following should be administered every hour in teaspoonful doses: Tinct. aconiti, m. iv; spirit ether nitrosi, 3j; aqua, q. s. ad., 3j. The chest should be thoroughly rubbed with camphor oil 3 times daily. The bowels should be thoroughly moved with calomel, followed by castor-oil, and for the distention of the abdomen by gas, enemas, carminatives, and castor-oil should be given. If the attack is not aborted by these means, a mustard paste (1 part of mustard to 6 of flour) should be applied to the chest every 3 hours for half an hour. If the soreness is not then relieved, inhalations of plain steam, or steam from lime water; or, what is better still, a tablespoonful of compound tincture of benzoin or a few drops of creasote to the pint of water can be put into the croup-kettle and the steam inhaled. This can best be done by the use of the "bronchitis tent." During the first stage, before secretion has been established, the following will act as a sedative to the inflamed mucous surfaces: Syrup ipecac, 3j; potass. citrat., 3iv; aquae, q. s., 3vj. One dram every 3 hours. During the second stage remedies should be used to stimulate the bronchial tubes and increase the volume of liquid poured out, such as: Ammon. chloridi, 3ij; ext. glycyrrh. fl. 3ij; aqua, q. s., 3ilj. One teaspoonful every 4 hours. [C.A.O.]

4.—The sanitary needs of Panama are noted by M. L. Maduro. He calls attention to the fact that as an interoceanic ship canal is to be built through the Isthmus of Panama, it is essential that the sanitary needs of the towns through which the ditch will be dug should be given first thought. Panama possesses no aqueduct, but depends on the heavy rains for its water-supply. Well-ventilated sewers should be built, and a system of up-to-date plumbing installed. The rookeries occupied by the very poor should be replaced by well-ventilated dwellings, of however cheap construction, and an efficient street cleaning department should be organized. The blind and narrow streets should be opened to the sunlight. Strict quarantine regulations must be enforced. A systematically equipped Board of Health is essential, the duties of which in the broadest sense should be to teach cleanliness as it affects air, water, and food. [C.A.O.]

Medical News.

February 13, 1904. [Vol. 84, No. 7.]

1. Abdominal Pain of Intestinal Origin. FREDERICK HOLME WIGGIN.
2. The Dietetic Treatment of Arteriosclerosis. THOMAS L. COLEY.
3. Enlargement of the Phalanges in Rickets: A Report of Two Cases. JACOB SOBEL.

4. Treatment of Pneumonia. DELANCEY ROCHESTER.
 5. The Sanitary Aspect of Food Preservatives. R. G. ECCLES.

1.—Abdominal Pain of Intestinal Origin.—Frederick H. Wiggin says the importance of a correct interpretation of abdominal pain of intestinal origin can hardly be overestimated. Abdominal pain, if sharp, and persistent, indicates involvement of the peritoneum, but if dull and aching it points to connective-tissue involvement only. Tenesmus indicates limitation of disease to the lower third of the intestinal tract, whereas colicky pain, occurring several times a year in a person not habitually constipated, suggests enterostenosis. The author deals with the various pathologic affections which are likely to involve the intestine, and sums up by stating in part that the chief value of abdominal pain as a diagnostic symptom in intestinal conditions is not only to indicate that the patient is suffering, but it enables the surgeon to locate the seat of trouble. Many lives will be saved, and thousands of others made more comfortable when physicians generally come to recognize that in all cases of persistent abdominal pain of obscure origin, exploratory operations should be performed, for it has been the writer's experience that a cause always does exist when such a pain is present, and that it is usually found with ease when looked for; in other words, when in doubt, operate. [A.B.C.]

2.—Dietetic Treatment of Arteriosclerosis.—T. L. Coley discusses the etiology of arteriosclerosis, which may affect the circulatory system in any or all of its parts. The damage done cannot be repaired. The physician can endeavor simply to arrest the process and prevent complications. Muscular work should be kept at the point of merely maintaining the cardiac hypertrophy and muscular nutrition. Persons with great responsibilities should have frequent vacations. Obese patients accustomed to overfeeding generally exercise little, are flabby and constipated. The autointoxication resulting and the overstimulation of the splanchnic nerves both increase arterial tension. We should aim at loss of weight and increased muscular tone. Some patients use foods too rich in nitrogenous elements and extractives. Theoretically, foods rich in limesalts are contraindicated, but it is doubtful whether the amount ingested can increase the amount assimilated. It is always imperative to reduce the amount of fluids whether alcoholic or nonalcoholic, these causing overdilatation of the bloodvessels and irritating the splanchnic nerves. If the alcohol habit cannot be broken, spirits or wines, but not malt liquors, should be used. We must restrict uric acid producing meats and avoid liver, kidney, and sweetbreads. [H.M.]

3.—Enlargement of the Phalanges in Rickets.—J. Sobel finds very little mention of this deformity in literature, and reports 2 cases with illustrations. The enlargement is in the diaphysis. Syphilitic lesions are at the junction of diaphysis and epiphysis. He believes the condition is frequently overlooked. He would designate the lesion as rachitic dactylitis. Radiography has demonstrated that the enlargement is periosteal. [H.M.]

4.—Treatment of Pneumonia.—D. Rochester briefly reviews the clinical course of a favorable case. Treatment in pneumonia must be directed to relieve the toxemia, prevent heart failure, and meet complications as they arise. As the kidneys are involved, they should not be stimulated to greater activity. The sweat at the crisis and occasional critical diarrhea point to the skin and bowel as preferable avenues of elimination. Catharsis is best produced by calomel and salts. Sweating is most easily induced by the mustard foot-bath scientifically given. The patient lies with flexed knees between blankets, the long axis of the tub in the line of his body and legs; another blanket passes from under the tub up over the end and over the knees; 2 to 5 blankets with a rubber sheet are placed over the patient, and the foot of the bed and tucked in. The tub at first is filled half full of hot water with a heaping tablespoonful of mustard; more water is added from time to time, and the bath kept up from 30 to 45 minutes, while ice cloths are placed on the patient's head. To prevent further bacterial invasion, the mouth should be frequently cleansed with a mild antiseptic solution. The diet should be fluid, with plenty of water to flush the excretory organs. Leeches or cups

should be applied over each congested area as it develops. With evidence of overdilatation of the right heart 8 to 12 ounces of blood should be taken from the arm. When heart failure is, in spite of this, imminent, subcutaneous injection of salt solution is sometimes valuable. [H.M.]

5.—Food Preservatives.—R. G. Eccles believes that vinegar, salt, alcohol, and smoke, possess no antiseptic properties superior to those articles which biased people wish suppressed by law. He notes the relation of salt to scurvy and its poor bactericidal properties. No death from salicylic acid is reported. In the quantities used as preservatives experience demonstrates their harmlessness. Statistics show a much lower deathrate in cities where preserved foods are most largely eaten than in the rural districts in the matter of gastrointestinal disease. Beer drinkers are shown to be freer from these diseases than the more abstemious classes of the community notwithstanding the common use of salicylic acid therein. [H.M.]

CLINICAL MEDICINE

DAVID RIESMAN

A. O. J. KELLY

EDITORIAL COMMENT

Typhoid Fever.—Following the usual custom of issuing a special number in each volume, the editor of the *Practitioner* has devoted the entire January number to articles dealing with some phase of typhoid fever. Sir William Broadbent contributes introductory remarks in which he states that typhoid fever in an especial manner affords scope for watchful care, well-informed judgment, and prompt intervention. The great service rendered by the thermometer has led in everyday practice to much laxity of observation in other respects and too frequently the temperature, instead of the disease, has been treated, this being even worse than treating the disease only and not the patient. The prevalence of typhoid fever abroad is discussed by Drs. F. M. Sandwith, A. Duncan and J. Cantlie in articles on that disease in Egypt, India and China, respectively. While Egyptians, especially the rural inhabitants, enjoy a comparative immunity to typhoid, it is being recognized that cases of the disease are not extremely uncommon. Winter, instead of autumn months are most productive of cases. Though it was formerly stated that typhoid did not occur among the natives of India, the contrary can now be positively asserted. The symptoms vary considerably from the classic picture, Duncan having seen a typical temperature chart in but one instance. Among the English population of India the disease is constantly increasing. Cantlie says it may be safely affirmed that Chinese adults are rarely attacked by typhoid and there is insufficient evidence to confirm the belief that children early acquire the disease and thus become immune. "Reflections on Typhoid Fever in Camps" is presented by Dr. H. H. Tooth. "The Etiology and Prevention of Typhoid" is considered by Drs. G. Newman and H. E. L. Canney. The former cites numerous concrete cases to show that spread of the disease is not at all infrequently due to infection by contact with previous cases. A second common means of infection is that of contaminated food, particularly shellfish. The writer concludes that in London, of which he writes, water-borne infection is not the chief channel, and that the two methods previously mentioned are the principal factors in spreading the disease. In connection with the above reference to the importance of shellfish in the propagation of typhoid fever, we wish to call attention to an article by Dr. Nash,¹ Medical Officer of Health for Southend-on-Sea. During the years 1902 and 1903 there were reported 798 cases of infectious diseases. Of these, 88 patients admitted having recently eaten or handled oysters, cockles or mussels, and of these 88 shellfish consumers no less than 94% were cases of typhoid fever. Following this article in the same

¹ Public Health, November, 1903.

journal is one by Major Caldwell on the "Causation of Enteric Fever Apart from Water Supply." From facts personally observed in Egypt and South Africa, given in detail, he reaches the conclusion that the only plausible explanation is that the colon bacillus underwent transformation into *B. typhosus* in the soil of various camps that had been long occupied. The water supply appeared to have little or no influence in the outbreaks. We mention these points to emphasize the fact that, though water is undoubtedly a source of infection, the occurrence of extensive epidemics, as the recent outbreak at Butler, Pa., is apt to magnify in the minds of the profession the part played by water supply in the continuous production of sporadic cases of typhoid fever. We should by all means exercise eternal vigilance regarding the water supply, but other possible sources of infection need to be just as actively investigated and removed. The contribution of Dr. Charles Bolton to the symposium in the *Practitioner* is upon "Rigors in Typhoid Fever apart from any Recognizable Complication." He reports a case, in a female of 24, in which 21 well-marked rigors occurred. The case is believed to lend support to the view that some irritation of the intestinal mucous membrane is the etiologic factor in a large number of the cases of this kind. Rigors are not usually of serious prognostic import. An article on "Antityphoid Inoculation," by Dr. A. E. Wright, is to be concluded. The treatment of typhoid is discussed by Drs. J. W. Moore, H. P. Hawkins, H. Mackenzie and Thomas McCrae (Baltimore). Each presents a plain, concise article that is well worthy of much more extended comment than our space allows collectively. The first writer lays particular stress on the value of sanitary housing in the treatment of typhoid fever and on the necessity of extreme caution in the primary cleansing of the intestinal tract that strong purgation may be avoided. A drug considered far superior to salol as an intestinal antiseptic is salicylate of quinin. Young physicians are warned against the error of adopting a routine treatment of cases. In speaking of the early diagnosis of perforation, Mackenzie says that abdominal pain is by far the most important of the early symptoms. Confirmatory general signs are change in the temperature, pulse or facies. Confirmatory local signs are abdominal tenderness or rigidity, obliteration of liver dullness, shifting dullness in the flanks, and diminished respiratory movement of the abdominal wall. Leukocytosis is considered of negative rather than positive value. In summing up the treatment of typhoid in Dr. Osler's wards, McCrae states that one of the slogans is "more water." A minimum of 3 liters (quarts) of fluid per day is the rule. Many patients take 6 liters or 7 liters daily. Too little food rather than too much is the rule. The bath treatment is employed in nearly all cases. A state of constipation is preferred. Laparotomy for typhoid perforation should almost always be done under cocaine. A summary of our present knowledge regarding paratyphoid fever, by Dr. R. T. Hewlett, and several pages of editorial comment on the subject of typhoid fever, close this very valuable series of additions to our literature on a world-wide disease.

REVIEW OF LITERATURE

Absence of Casts in Urine of Nephritics.—A. Treutheim,¹ after observing a case of nephritis with albuminuric retinitis, but without casts, performed some experiments to determine the cause of this phenomenon. He formulates his conclusions as follows: 1. There are cases of typical nephritis with albuminuria and albuminuric retinitis, in which no casts can be demonstrated in the urinary sediment. 2. This condition, which must be considered as a cylindrololysis, is not due to the pepsin excreted by the kidneys. 3. The leukocytes of an existing cystitis, which have ascended to the pelvis and the uriniferous tubules, are not capable of dissolving casts. 4. Pus

cells from kidney abscesses cannot do it. 5. It is probably due to bacterial action (bacterium coli). This may take place in the bladder, or with greater probability through ascension of the colon bacilli already in the pelvis or renal ducts. 6. The ferments of the bacterium coli do not have the power alone of dissolving casts. [E.L.]

Forms of Relapse in Typhoid Fever.—M. Coste¹ describes the different forms of relapse in typhoid fever. First there is the regular form, in which the relapse repeats the primary attack, usually with less severity and less pronounced symptoms. The rash reappears on the second to fifth day, and the relapse lasts 3 to 4 weeks. Then there is the febrile relapse without any typhoid symptoms or complications to account for the fever; the rash may not reappear in this form. There is an irregular form in which the temperature rises and falls, sometimes below normal, for 2 to 3 weeks; the rash is also irregular in its appearance. Another form of relapse is characterized by an abnormally large, daily oscillation of the temperature; the typhoid symptoms may not be well marked, but the attack may last from 3 to 4 weeks. There is an abortive type, in which the fever lasts only from 7 to 9 days, and the rash may appear toward the end, or even after the temperature falls to normal. [B.K.]

Lime Absorption of Animal Tissue and the Causation of Rickets.—M. Pfandl's² experiments show that if animal cartilage or bone in either living or dead matter is brought in contact with neutral solutions of calcium chlorid the lime gradually disappears from the solution, the chlorids remaining intact. Gelatin solution and inorganic lime plates possess the same properties. With other experiments he proves that newly-formed osteoid tissue does not have a special affinity for the inorganic components of the bone masses formed later, but that this affinity appears during transformation of the osteoid tissue, and that for this calcification a special form of heteroplasia is necessary. The cause of rickets can from this be deduced to be a change in the osteoid tissue which prevents it from taking up lime, and not, as has been claimed, a lack of lime in the diet. Bones deprived of their lime artificially will take up calcium. The process in rickets is a prevention of normal, biochemical tissue changes. [E.L.]

Treatment of Diabetes.—R. Hutchinson³ defines diabetes as permanent glycosuria. By getting rid of the sugar we are not masking symptoms, but curing the condition, as the sugar in the blood impairs still further the power of dealing with carbohydrates. Thirst, pruritus and eczema, suppurations, cataract, retinitis, perforating ulcer, neuritis, etc., are directly due to the sugar in the blood. Carbohydrates should be withdrawn gradually to prevent coma. Fat is the only true and safe substitute, though most diabetics seem inherently unable to digest it. This is, perhaps, one reason why they become diabetic. Those fats most easily digested are cream, butter, bacon, and salad oil. Gluten bread is too light, and contains starch. Casein preparations are the best. The writer recommends "Casoid Meal Bread." He has had a milk without lactose prepared. Alcohol yields heat and helps fat digestion. Malt liquors are contraindicated. In mild cases never allow patients to take carbohydrates up to the limit of their assimilating function. In the severer cases, carbohydrates may be prohibited so long as weight and appetite are maintained. When sugar persists, formed from the proteid of the food and tissues, and β -oxybutyric acid is present it is well to allow a moderate amount of carbohydrate food as a fat carrier, but from time to time these patients should be put to bed on strict diet. [H.M.]

Pathologic and Antitoxic Treatment of Tetanus.—E. v. Behring⁴ gives much valuable information about tetanus in this short paper. The greater part of the tetanus poison injected into an animal enters the lymph-vessels and from there the blood circulation. The smaller part is absorbed by the terminal nerve filaments, reaches the axis cylinder and travels centrally along intact axis cylinders to the motor ganglion cells of the spinal cord. The poison absorbed by the blood also reaches the central nervous system and produces generalized

³ Edinburgh Medical Journal, October, 1903.

⁴ Deutsche medizinische Wochenschrift, 1903, xxix, No. 35.

¹ Münch. med. Woch., Vol. I, No. 35, 1903.

tetanus. It is absorbed by a portion of the protoplasm of the ganglion cells, and not only is it absorbed by the protoplasm of motor ganglia, but also sensory and sympathetic ganglia. The antibody acting against the tetanus poison is not an antibacterial, but an antitoxic; it may be used as a medium for the growth of tetanus bacilli. The neutralization of the poison is brought about by a destruction of the poison by the ferment action of the antitoxin, and not by combination between toxin and antitoxin in certain proportions. The fermentative action produces a third substance, which the author calls a conductor. Behring announces that every flask of his antitoxin is tested regarding its experimental antitoxic value, its curative and protective value; 100 units are its curative dose, 20 units should be injected in all cases where a wound has been received which may terminate in tetanus; as it disappears fairly quick, this must be repeated, new tetanic toxin is produced at the infected focus. It is prepared as a fluid for injection and as a powder for dry application to wounds. The sooner the antitoxin is used after the development of the disease, the greater the chances of the patient's recovery. In spite of the fact that in most cases it has not been used until very late, the mortality figures of tetanus have been reduced by antitoxin from 88% to 45%, and he concludes, that were it employed very early in all cases, this mortality would disappear, as the diphtheria mortality has disappeared. [E.L.]

A New Inhalation Method of Treating Tuberculosis.—L. Danelius and Thomas Sommerfeld¹ refer to the large number of preparations offered for the treatment of pulmonary tuberculosis, nearly all of which have failed to give the results claimed for them. While traveling in Australia, R. Schneider was impressed with the benefit derived by the natives in treating tuberculosis by means of a decoction of eucalyptus leaves. He prepared a powder from that plant and called it "Sanosin." This powder is administered by means of inhalations; it is allowed to burn in a vessel over an alcohol lamp for 15 minutes. The fumes which arise are inhaled during the entire night, and for several hours during the day. The windows and doors of the room should be tightly closed, so that the vapor will not escape. Relief after these inhalations is first noticed by the decrease in the cough and in the amount of expectoration. Insomnia disappeared, and in the authors' cases no sedatives were required during the treatment. After a few weeks the night sweats ceased, the appetite and body-weight increased, and the bacilli disappeared from the sputum. The authors give the case histories of 13 patients, all of whom were considerably relieved by the above method. [W.E.R.]

Two Cases of Stokes-Adams' Disease.—Rochemont's² first case showed a diminution in pulse-rate, not because of deficient cardiac contraction but because every second contraction was so weak as not to produce a pulse wave in either the carotid or radial artery. The cause of the disease in this case could not be determined absolutely. Against cardiogenic origin spoke the length of time the condition had existed (5 years), the regular irregularity of rhythm and intensity, the normality of the second pulmonic sound, and the fact that exertion did not influence the patient's state. The lesion most likely is situated near the vagus center, as there was always a simultaneous participation of all the pneumogastric terminations (oppression, gastric pain, respiratory disturbance, and dizziness). In the second patient an insufficiency of the left ventricle was suspected, as the pulse and heart tracing differed. In addition to marked irregularity, which was the same on both tracings, the pulse tracing shows the absence of some ventricular contractions, which are seen on the heart tracing, and in no case are the radial contractions as well marked as the cardiac. [E.L.]

Symptomatology of Thrombosis of the Renal Veins.—H. Reese³ reports a case of thrombosis of one of the renal veins, and reviews the literature. He draws the clinical picture as follows: Pains in the region of the kidney, marked albuminuria, usually hematuria; enlargement of the affected kidney; transient diminution in the amount of urine and increase in its specific gravity; usually a rise in temperature. If

recovery occurs the symptoms gradually disappear. The healthy kidney may take over the function of the other, and the symptoms may disappear. If the thrombus forms slowly, collateral circulation may develop. In the case reported, chlorosis was the cause of the thrombosis, and recovery occurred. [B.K.]

Sugar Combustion after Removal of the Entire Pancreas.—To determine why the gravity of the diabetic state varies in different animals after pancreas extirpation, and whether other organs beside the pancreas help in using up sugar, H. Luethe¹ removed the pancreas of several dogs, and placed them on absolute starvation after the operation. After no sugar was found in the urine there was still sugar in the blood, thus proving that in this case sugar was burnt up by the organism. The dog was given nitrogenous food and the sugar at once reappeared. As a histologic examination of the duodenum showed well-preserved microscopic remnants of pancreas, the combustion of the sugar may have been carried on by it. In his next experiment he removed the pancreatic segment of the duodenum as well, with the same results in regard to sugar combustion. Animals, therefore, whose urine after pancreatectomy has been made sugarless through starvation, are still burning up sugar, as proved by the presence of sugar in the blood. Which organ does it? The fact that sugar disappeared from the urine only after the dogs were placed upon diet absolutely free of nitrogen, shows the dependence of a diabetic state upon the nutrition of the patient. [E.L.]

Empyema in Infants.—E. Guglielmetti² considers latent or insidious empyema occurring at the base of the lung in children or infants. There the lesion may escape detection. But the health of the child deteriorates. Considerable space is given to symptoms and attention drawn to the danger of carelessness leading to the confusion with marasmus in the event of neglect of physical signs. Tuberculous infection is discussed. Upon such a child the effects may be both indirect and toxic, as well as direct and microorganismal. Prognosis is unfavorable; early diagnosis difficult, and treatment being only of moderate success. [T.H.E.]

EDITORIAL COMMENT

Radium and Röntgen Rays in the Treatment of Inoperable Carcinoma.—The sensational reports which have appeared in the daily papers of late are of the kind that usually appear when any new thing is introduced in the treatment of disease; they always do harm by arousing the expectations of credulous people, only to disappoint them in a large measure. That much has really been accomplished in the treatment of inoperable malignant growths by the use of the röntgen rays no fair minded person can doubt, and reports which are beginning to come to us seem to indicate that the radium rays may also be of some value. An interesting review of the more important work which has been done all over the world is given in a recent paper by Dr. Truman Abbe.³ He discusses the physiologic action of radium rays and tells us that the activity of a specimen is estimated by the time required for the salt of chlorid of barium and radium, which is commonly used, to discharge a gold-leaf electroscope. The time required for the discharge of such an electroscope by metallic uranium is taken as the standard and if the specimen of radium discharges the instrument in a thousandth of the time required by the uranium the strength is taken as 1,000. Specimens of high strength are usually employed; anywhere from 1,000 to 300,000. The rays differ considerably from the röntgen rays; the photographs made by them are blurred in outline so that the rays are not likely to supersede the röntgen ray for this

purpose. Like the röntgen ray, they inhibit the growth of certain bacteria, but this is of doubtful practical value. Brief summaries are given by Abbe of 32 cases of inoperable carcinoma, which have been treated by surgeons in different parts of the world by the use of the röntgen rays. Many of these were apparently much improved, at least temporarily, and two or three were apparently cured. A number who have experimented with the radium rays report better results than with the röntgen ray, though, of course, they have not been used for a long enough time to give sufficient material as a basis for fair comparison. Dr. Robert Abbe, of New York, treated a case of epithelioma with the röntgen ray and radium rays, covering half the growth with lead while using the röntgen ray, then reversing the lead covering, and treating the other half with radium. During the first week the radium had the advantage, then for some reason the röntgen ray took the lead and at that point, to hasten the results the entire area was put under the röntgen ray treatment, and was completely cured with a good, cosmetic effect. It can hardly be expected that one in ten of the cases treated will be cured, though this is the proportion in the cases thus far reported, but we confidently expect that there will be a large enough percentage of cures to justify the use of this treatment. Members of the medical profession should certainly make use of these and other means of treatment of inoperable carcinoma which are at hand, for if patients are given no encouragement whatever, they are almost certain to fall into the hands of quacks and irregulars, who fleece them, and usually add to their sufferings without in any way improving their condition. No one can question that certain cases of inoperable carcinoma are apparently cured, in a small proportion of cases, by the use of the röntgen ray, Adamkiewicz serum, and the use of certain caustics. All of these means are very uncertain, and should never be used in cases suitable for operation, but in inoperable cases they can be used, and the patient given assurance that a number of cures have resulted from their use. From the small amount of experience which has thus far accumulated, we judge that radium will prove a valuable addition to the list of therapeutic measures which we already have for use in such cases.

REVIEW OF LITERATURE

Evacuation of Gallstones by Flushing of the Biliary Passages.—F. Kuhn¹ employs these flushings during the operation and through existing fistulas under a pressure of from 200 mm. to 1,000 mm. of water. Normal salt and other solutions come in use. The purpose is a three-fold one—diagnostic, medicinal and mechanical. He has found that if a stream of 25 cc. under a pressure of 50 c. does not enter freely an impediment exists, between 50 cc. and 100 cc. indicate very wide passages. Small calculi may be removed through this flushing and often are; large ones are not. At times it may be necessary to use high pressure with simultaneous injections of morphin and atropin to remove foreign bodies from the passages. In 1 case he removed all the stones he could find during operation, and during this rinsing he was able to bring away about 40 more, which had come down from the upper passages. By using this means we simply produce an artificial gallstone colic, arranging our pressure however, as we wish to and continuing the process only as long as we want to. Gallstone colic, it must be remembered, is only an expression for an increased pressure along the biliary passages, produced through an impediment to the free flow of the biliary secretion. [E.L.]

Gunshot Wound of the Stomach.—E. Forgue and E. Jeanbrau² conclude a paper begun in the September issue. They consider in order the following points: The area of gastric vulnerability, the principal lesions that may result from a projectile penetrating this area, the frequency and variety of the visceral lesions that may accompany perforation of the

stomach and mask the symptoms, aggravate the prognosis, and increase the difficulties of intervention; the proportion of cures following operation, according to the presence or absence of accompanying lesions and the time of intervention. They present a table of 152 collected cases, which are grouped into those treated by laparotomy and those treated by expectation. The summary shows that the mortality from gunshot wounds of the stomach, without accompanying visceral lesions, treated by expectation, was 46%; treated by operation, 42%. In the cases with accompanying visceral lesions treated by expectation, the mortality was 93%; treated by operation, 68%. The general, though not absolute rule, for treatment is that when a person receives a bullet wound in the left hypochondrium or the epigastrium, laparotomy should be immediately performed. Death is not certain if the abdomen is not opened as spontaneous cure has occurred, but it is not possible to say what case will have this fortunate termination. The article closes with a discussion of operative technic. [A.G.E.]

New Method of Hip-joint Amputation for Sarcoma.—Cornelius A. Griffiths¹ reports the case. The patient was a girl of 16 suffering from a large sarcoma of the right thigh; the patient refused operation until in a condition of great emaciation and systemic depression, though recovery followed. The interesting feature in the case consists in the method of amputation. The vertical rim of a racquet-shaped incision was commenced 5 cm. (2 in.) above the trochanter, and into this incision at its upper end was inserted the smooth blade of a pair of long forceps; this was pushed inward parallel to Poupart's ligament for its whole length and immediately in front of the hip-joint and the femoral vessels, the other blade being outside the skin, the forceps were then closed, thus clamping the vessels in what would become the anterior flap. Another pair of forceps was used, the deep blade passing beyond the neck of the femur; these controlled the circulation of the posterior flap. The oval part of the incision was now marked out and cut, muscles divided, the joint opened in front and limb removed as is usual. The vessels which could now be seen were ligated without difficulty, and the wound closed in the usual manner. The author believes that his is a distinct improvement in technic for preventing hemorrhage in amputation at the hip-joint. [A.B.O.]

Massage in the Treatment of Recent Fractures.—Jordan² practises stroking massage from the very onset of a fracture, and as soon as possible adds passive movements to it. He reports his results in 73 patients, 40 of whom suffered with fracture of the radius. Of the 73 patients, 27 had passed the fortieth year. Full return of power was noted in 67; the other 6 were more or less incapacitated. He sums up his experiences as follows: All fractures of the upper extremities are suited to massage and passive movements; if it is a fracture into a joint or the shaft is but slightly dislocated, fixation must follow each treatment; if there is considerable dislocation of fragments, massage must be associated with permanent fixation until sufficient callus has formed. In fractures of the lower extremities, massage must be limited to joint fractures, and be combined with dressings suitable for walking. The pain disappears quickly, and the muscles are not permitted to atrophy. Cures are much more rapid and perfect with this method. [E.L.]

Diagnosis of the Site of Occlusion in Ileus.—E. Tavel³ concludes a lengthy article, begun in the August number, in which he first discusses the causes, symptoms and general diagnosis of ileus and finally the location of the site of the lesion. He believes that many questions regarding the diagnosis of obstruction, its location, and the propriety or not of surgical interference can be settled only by each surgeon reporting detailed studies of his individual cases. He practises his teaching by reporting from among his own cases 24 that illustrate certain points in diagnosis which are emphasized in the text. These cases include instances of obstruction of all of the principal parts of the intestine and are given in order, beginning with the pylorus and ending with congenital atresia of the anus. This valuable contribution, of which even the salient points cannot be enumerated in a brief abstract, closes with a

review of the symptoms of occlusion classified under (1) general symptoms; (2) symptoms furnished by the intestine and peritoneum; (3) symptoms furnished by local examination; (4) symptoms of occlusion of different points in the intestinal canal. Under the latter are included 10 different sites. [A.G.E.]

Traumatic Hernia of the Lungs without Penetrating Wound.—A. Bickel¹ reports the case of a man who received a blow on the left side of the chest, which fractured several ribs. No external wound was produced, but the development of bloody expectoration and subcutaneous emphysema showed that the pleura and lungs had been wounded. The immediate results of the contusion disappeared, but examination of the patient more than a year later showed a hernia of the lung had developed. The hernial opening consisted of a widening of the fourth left intercostal space just below the nipple. On forced expiration a swelling appeared in this region, which evidently contained pulmonary tissue. [B.K.]

Hard or Soft Paraffin for Subcutaneous Injections.—E. Stein² is a firm defender of soft paraffin; its melting point should never be more than 41° C. (105.4° F.). Harder paraffin should only be employed in cases where large cavities with firm walls require obliteration. In all other cases it is contraindicated, as it increases the danger of embolism. The material should never be injected in fluid state, but always while in a pasty condition. He never injects more than 3 cm. at a sitting. The mass, as proved by animal experiments, is not absorbed, but encapsulated, and separated into compartments by connective-tissue trabeculas; this shows that the result in each case is a permanent one. Immediately after injection slight edema appears; this disappears regularly within a few days. By injecting too much at a time, cutaneous gangrene may be produced. [E.L.]

Chylous Cyst of the Ascending Mesocolon.—Meriel³ says that notwithstanding progress in the science of diagnosis there are certain abdominal cases in which the knife is the only means of diagnosis; in still other cases the origin of the tumor cannot be determined even after the abdomen has been opened. The case which he reports belongs to the latter class. The patient was a robust woman of 45, who had had an abdominal tumor during 10 months which had been diagnosed as ovarian cyst. On her entrance to the hospital the tumor, which was the size of an adult's head, occupied the right flank and iliac region. It was regular in outline, movable transversely, but not vertically, and followed the movement of the diaphragm. It was dull, except for a vertical band corresponding to the ascending colon. Vaginal and rectal examinations revealed no connection with the pelvic organs, and although doubt was felt the diagnosis of ovarian cyst was made. When the abdomen was opened in the median line, and the ascending mesocolon incised the tumor was easily exposed. The cyst was then punctured with a trocar, and 2 liters of a thick creamy fluid evacuated. The superior limit of the sac could not be located, but it was determined that the kidney was not involved. The anterior part of the sac was extirpated, and the posterior fastened to the abdominal wall. Abundant suppuration followed, but recovery was finally perfect. The histology of the cyst wall in connection with the other facts leads Meriel to decide that the condition was one of chylous cyst of the ascending mesocolon which had been immobilized by inflammatory processes in a situation where extirpation was impossible. The diagnosis of these conditions lies between that of chylous cyst and perirenal cyst. [A.G.E.]

Treatment of Prostatic Hypertrophy.—L. Casper⁴ reviews the results of treating 131 cases of prostatic enlargement. Out of 61 cases not operated on, 4 were cured, 38 improved, 8 not improved, 4 became worse, and 7 died. He divides his cases into 2 groups: One division includes those patients who are able entirely or almost entirely to empty the bladder, and the second division those who are unable to do so. Many patients do well when constantly catheterized, but in catheterizing it is important that the bladder be emptied slowly and not entirely at each catheterization; this is particu-

larly important in the absence of cystitis. The variation in tension of the bladder wall is one of the most potent factors in the development of cystitis. In the absence of the latter, catheterization should not be resorted to, unless there is as much as 300 cc. to 400 cc. of residual urine. Casper has not obtained very good results by vasectomy and castration. Bottini's operation does not always cure, but in 50% of his cases improvement followed this procedure. Electrolysis by way of the rectum was once recommended by him, but he now no longer practises it; nor does he have much confidence in puncture of the bladder or suprapubic cystotomy. In case of a small bladder, a permanent catheter should be used, and left in place for months. The end of the catheter should have a stopper, which may be removed when desired. The bladder should be irrigated twice daily, once with a silver solution of 1 to 1,000 or 1 to 4,000, and the other time with a solution of mercury in the strength of 1 to 5,000. Cases of prostatismus are difficult to treat. Instead of using a catheter in such cases, he resorts to hot sitz baths, thermophore compresses, soothing or narcotic remedies. Casper considers the operation of prostatectomy through a *sectio alta* too severe for any but young men with vigorous constitutions. [W.E.R.]

Lipoma of the Intestine.—S. B. Ward¹ reports 3 cases, two occurring in the service of Dr. McDonald. Ward's case occurred in a man of 37, who for some months had suffered from paroxysmal pain resembling biliary colic. He finally passed spontaneously from the bowel an egg-shaped mass, 11 c. by 4 c.; (4½ in. by 1½ in.) in size, that was found to consist entirely of fat in a connective-tissue framework. Complete relief from symptoms followed. Dr. McDonald's cases were in females of 29 and 50, respectively, the diagnosis being verified by operation in each. In one the tumor was in the jejunum, and had caused invagination of the intestine; in the other it was a sessile tumor in the cecum. Ward tabulates 37 reported cases of lipoma of the intestinal tract, and gives a brief review of each. The site of the tumors was: Esophagus, 1; stomach, 1; duodenum, 4; jejunum, 4; ileum, 5; small intestine (part not specified), 2; colon, 5; sigmoid flexure, 2; rectum, 2; retrorectal, 2; unknown, 9. The sex was, male, 16; female, 10; unmentioned, 11. Spontaneous expulsion occurred in 9 cases, invagination in 12. Death followed operation for the relief of the obstruction in 5, and in 1 case death was due solely to the obstruction. Nine cases were incidentally found during autopsy. [A.G.E.]

GYNECOLOGY AND OBSTETRICS

WILHELM KRUSEN

FRANK C. HAMMOND

REVIEW OF LITERATURE

Vaginal Drainage.—Goldspohn² thinks that abscesses occurring in the areolar tissue about the cervix over the vaginal vault, will usually make themselves known by some encroachment upon the vaginal cavity, and should be opened from the direction in which they point—into the vagina. Hematoceles, and sometimes circumscribed peritoneal exudates, when they become infected, will form abscesses that are readily accessible from the posterior culdesac and should certainly be evacuated into the vagina, and obliterated by means of suitable drainage into it. If there are inflamed appendages or nonpurulent exudates higher up, they are thereby given a better chance for spontaneous improvement or recovery; and in case a secondary celiotomy is required later it will be with less extirpation of adnexas and less mortality than would have obtained in a primary radical operation. More questionable is the proposition to drain tubal sacs which occur in distinctly organized lumina, lined with mucous membrane, or to drain ovarian abscesses because of their multilocular or honeycombed structure. But large unilocular tubal sacs can be emptied and packed; also ovarian abscesses whose honeycomb structure can be broken down by a finger into one cavity, may be drained and solidly packed. The gauze packing in these cases should remain in situ at least a week—first for drainage, and then its continued presence is needed to hold the walls of the sacs or

cavities widely expanded and to arouse a layer of granulation tissue upon by its irritation as a foreign body. In Goldspohn's experience most of the cases requiring a secondary radical operation after vaginal drainage, have been those in which the infection came from the vermiform appendix. A secondary operation was required in only 10% of the cases in which the infection came by way of the genital tract. [W.K.]

Relationship of Colon to Abdominal Tumors.—J. F. Baldwin¹ claims that the position of the colon in relation to an abdominal tumor is often an efficient aid in determining its origin. Tumors originating in either ovaries or uterus will be in the central region. The colon will be found in front of the tumor or toward its inner side. Tumors of the adrenals, or in the perirenal tissues, or from the Wolffian body, will produce an anterior or inward displacement of the colon. A tumor developing in a movable kidney usually appears outside the colon, though it may eventually enter the central area. The spleen must necessarily be on the outside of the colon, or, if greatly enlarged, will override it entirely. Bearing this fact in mind, there should be no difficulty in the differential diagnosis between tumor of spleen, kidney and ovaries. Enlargement of the liver crowds the colon down, also that of the gallbladder. Tumors of the stomach will, of course, crowd the transverse colon downward. Tumors of the pancreas are mistaken in the female for those of the ovary. But this mistake should be obviated by the fact that in 95% of these cases the tumor appears above the colon. [W.K.]

Creolin: A Note of Warning.—S. Rideal² says that the term creolin was invented many years ago as a fancy name for an emulsion of cresols and neutral tar oils in a soap solution and that different manufacturers have from time to time modified the nature and proportions of the various constituents without warning to the public. The carbolic acid coefficient of samples of creolin purchased in Brussels, Hamburg, and London was determined and the disinfectant value found to range from 1½ to 16 times that of pure carbolic acid. Chemic examination showed the samples to differ widely in their percentages of tar acids and neutral oils. These figures are not proportional to the bactericidal efficiencies, however, and a valuation based on their content of tar acids alone would be entirely erroneous. Their bromin equivalents are likewise of no value for this purpose. The Germans have made some efforts to distinguish between different grades, but have not entirely succeeded. Rideal thinks that if the term creolin is to remain in the literature of the subject, a statement of the germicidal value of the disinfectant in terms of some standard should be insisted on in all cases. [A.G.E.]

Treatment of Hematocele.—Paul Zweifel³ asserts that the rupture of the tube is not by any means always delayed until the third or fourth month, citing a case in which the hemorrhage occurred only 8 days after the first omission of the menses. Thus the ovum could not have ruptured the tube by distention, and as it had reached the serosa and grown through it into the abdominal cavity, it must have done so by an active process. Several cases have been recorded in the Leipzig clinic in which the placenta had undoubtedly grown through the wall of the tube, and even through the peritoneum. The true explanation that in tubal gestation the ovum almost invariably eats its way into the tubal musculosa has been established as a fact by the researches of Fuetth, Aschoff, Kuehne, and many others. Whether the hemorrhage that follows is moderate and the blood soon encapsulated by clotting, or whether it pours into the peritoneal cavity to such an extent as to endanger life, is a mere chance. Moreover, the capsule of the ovum may give way first in the tube, blood may pour through the abdominal ostium, and a tumor be formed in the Douglas' pouch, yet the ovum may continue to grow and afterward eat through the tube wall in another place. When a pregnant woman is attacked with symptoms of peritonitis—that is to say, with great pain in the hypogastrium, swooning, collapse, vomiting, decreasing volume of pulse, if there be no fever, an erosion of a gravid tube must be at once suspected, and immediate operation accepted as absolutely necessary. [W.K.]

Fifty Cases of Artificially Interrupted Pregnancy.—These cases are reported by R. Karb.¹ The indications for artificial interruption of pregnancy fall into 2 groups. The first includes those conditions threatening the life of the mother; and the second group comprises the contracted pelvis in which an attempt is made to save the life of the fetus. The first group included nephritis of pregnancy, 10 cases; nephritis and eclampsia, 2 cases; heart disease, 5 cases; tuberculosis of the lungs, 10 cases; purulent bronchitis, 1 case; pernicious vomiting, 3 cases; hydramnios, 1 case; grave hysteria, 2 cases; movable kidney and cholelithiasis, 1 case. The group of contracted pelvis included 15 cases. Seven of the cases of nephritis were greatly benefited by the interruption of pregnancy, as were also 4 cases of heart disease and 7 cases of tuberculosis. The maternal mortality in this first group of cases was only 8.57%, in spite of the serious diseases involved. The fetal mortality was 70.9%. Of the second group, 6 patients had flat pelvis, and 9 were generally contracted. All the mothers recovered, while the fetal mortality here was 53.4%, which the author considers very unsatisfactory. [B.K.]

Shortening the Round Ligament.—H. W. Longyear² describes the technic of shortening the round ligament by the blunt hook operation, and believes that this offers the patient the most for the least risk. The operation is applicable only in cases of mobile uteri without diseased appendages—in which cases it is an ideal procedure—or in cases in which adhesions may have been broken up previously by an abdominal operation. A tabulated record of 58 cases is given, only 4 of which were partial or complete failures. The interior of the uterus should be examined with the curet in all cases that have not been curetted at a recent date. Occasionally a curet is not necessary, but usually the uterus which has been in retroversion some time will be found to contain more or less degenerated mucosa. [W.K.]

Selection of Methods in Abdominal Hysterectomy.—H. A. Kelly³ urges conservatism in some of the worst pelvic abscesses. In relative value to a woman the tubes are least, the uterus next, and the ovaries the most important. With removal of the tubes only conception goes, but menstruation, ovulation, and internal secretion are retained. If the ovaries must go it is better to remove uterus and tubes also. In hysterectomy the round ligaments should always be tied to prevent slow hemorrhage. [H.M.]

Lacerations of the Cervix and Their Consequences.—J. W. Taylor, of Birmingham,⁴ says that in most of the septic cases to which he has been summoned he finds serious laceration of the cervix, of the vagina, and of the peritoneum as the wounds from which the septic and generally fatal process has started. The greater number of minor lacerations of cervix heal without consequences; but those of a major degree may cause sepsis, subinvolution, serious menorrhagia, uterine descent and flexion, cervicitis, abortion, sterility, atrophy of the uterine wall at the highest limit of the tear and finally epithelioma. The troubles due to uterine lesion, only, can all be completely cured by repair of the laceration, combined with a preliminary curetment. A wedge-shaped excision of the cervix is often needed before the lacerated parts can be brought together, and the angle of the tear needs complete excision. When the injury extends into the vaginal roof and broad ligament, something more than repair of the uterus is needed, as the faulty position of the uterus, the cicatrix in the broad ligament and consequent dragging are still sources of pain and discomfort. In such cases, he has sometimes tried to reattach the broad ligament to the cervix at its proper level, but with only partial success, and in the worst of these the only thorough relief to be obtained is by removal of the uterus. [W.K.]

Vaginal Cesarean Section.—Duehrssen's operation, on account of delayed labor and premature amniotic breaking, is reported by Proubasta.⁵ The patient, long neurasthenic, had suffered an unusual series of accidents, and the irregular progress of the case is curious. Following extraction of the fetus,

which lived, there seems to have occurred maternal infection, for cultures developed staphylococci and streptococci. Then the mother acquired a panophthalmitis with ocular complications of extreme gravity, succeeding its cure. After some months complete health was attained. [T.H.E.]

Causes of Death following Pelvic and Abdominal Operations.—J. Price¹ thinks that many deaths are due to incomplete operations done by incompetent and untrained operators. This is especially true in many small hospitals throughout the country; and he advises his pupils and friends not to undertake complicated and unpromising operations, but to allow more experienced operators to do them. Vaginal incisions and perforations favor a high mortality in later operations made for the clean removal of the remaining pelvic pathology. The choice of method and material is of paramount importance to good work, and the suprapubic procedures, when complete and done early, drainage used when necessary, should give a mortality close to nil. In suppurative forms of tubal and ovarian disease, Price does not consider the vaginal route as complete surgery; the adherent omental and bowel adhesions and the diseased appendix are wholly neglected. The anesthesia is important though he has little choice between ether and chloroform, but a good anesthetist is important. He emphasizes also the importance of good after-care. His nurses keep his mortality down and we should pay even more attention to this specialty. In regard to material Price considers the medical supply carpet bagger a dangerous man. The preparations of material by anyone in hospitals and used by clean well-schooled hands is safe and rarely gives mortality, but pure silk and silkwormgut are the safest and strongest of all materials. Gauze is a drainage dressing that takes the best care of the wound of all materials ever tried. Cleanliness and everlasting vigilance in cleanliness from the very inception of an operation, in patient, nurse, operator and environs, distances infection. [W.K.]

Reduction of Inverted Uterus.—R. Matas² gives in detail the technic by which an inverted puerperal uterus of 6 weeks' standing was reduced in one night by means of the colpeurynter. When the patient was seen the uterus was edematous and the mucosa presented a red, angry, strangulated appearance, bleeding at the least touch. It was decided to first check bleeding. The uterus was irrigated with hot 2% lysol and swabbed freely with hydrogen peroxid. With the patient in the knee-chest posture a 1 to 2,000 adrenalin solution was then applied to the uterine mucosa. A bag of iodoform gauze loosely filled with compound alum powder was then adjusted to the fundus and the vagina packed with gauze. When this pack was removed, 24 hours later, the uterus was much reduced in size, and all bleeding had ceased. After a hot douche followed by another application of adrenalin and peroxid, the patient was again placed in the knee-chest posture, a layer of iodoform gauze placed over the uterus and a large oval colpeurynter introduced into the vagina and inflated until the vaginal walls were fully distended. When the bag was removed, on the following morning, it was found that the inversion had been completely reduced. [A.G.E.]

The Gilliam Operation.—Since Gilliam suggested his operation 3 years ago, E. J. Ill¹ has performed 126 operations for retrouterine displacements, of which 86 were done by the Gilliam method. There were no deaths. A personal report has recently been received from 61 of these cases, and 51 report themselves as entirely well, 6 as markedly improved, and 4 as no better. Five were pregnant, and 2 had given birth normally. Only 1 case is reported as a recurrence of the displacement. In this case in opening the abdomen to ascertain the cause, it was found that that part of the round ligament beyond the suture was atrophied, while the near end retained its normal thickness. The atrophy was probably due to the fact that the ligature was drawn tight, strangulating the central artery. The writer modified the Gilliam operation by separating the rectus abdominis from its anterior sheath and then repiercing the rectus muscle, the inner sheath of the rectus, and the peritoneum. The ligament is then drawn out, as Gilliam taught, but

fastened to the posterior surface of the anterior sheath of the rectus with chromicized catgut, thus leaving the strong fascia intact. This was to prevent hernia. [W.K.]

Vaginal Cesarean Section.—M. Stamm¹ states there are over 60 cases of vaginal cesarean section reported, the majority of which were undertaken for cancer of the uterus, but the number performed for puerperal convulsions is increasing rapidly, and it seems that this trouble will furnish the chief indication for such operation in the future. Most authorities seem to agree that rapid delivery is the most important measure to reduce the mortality in eclampsia. He thinks that in vaginal cesarean section the incision is more under control and the wound gives more promise of healing by primary intention than the lacerations made by the use of Bossi's dilators or similar instruments. A longitudinal incision of 5 cm. to 7 cm. (2 in. to 3 in.) is made in the anterior wall of vagina, the bladder pushed back, a sagittal incision made through the anterior of the os, and through the lower segment of the uterus. Repeat this until, without opening the peritoneum, an incision of 8 cm. to 12 cm. (3 in. to 5 in.) is made. This is generally large enough to extract a mature child. If not, then make a similar incision in the posterior portion. In a majority of cases it is best to wait for the natural expulsion of the placenta, or if it does not follow soon, some pressure upon the uterus can be used. An illustrative case is reported. [W.K.]

Intestinal Obstruction Due to Ovarian Cyst and Pregnancy.—P. I. Kusmin² reports the case of a woman who suffered from an ovarian cyst, and who became pregnant. During the eighth month of her pregnancy, symptoms of intestinal obstruction suddenly supervened. Laparotomy was performed and the cyst found to be $3\frac{1}{2}$ times twisted on its axis. The tumor, the size of a man's head, was removed, and the patient recovered and went on to full term, being normally delivered of a heavy child. The site of obstruction was found in the sigmoid flexure, which had been tightly pressed against the pelvis by the tumor. The author adduces similar reports from literature, and concludes that pregnancy in a woman suffering from an ovarian cyst is an indication for immediate ovariectomy. If successfully performed, the operation has no deleterious effects on the further course of pregnancy and on labor, while without an operation the life of mother and child is in constant danger. The presence of an ovarian tumor may and often does escape the notice of the pregnant woman until complications arise. [L.J.]

E. LINDAUER

REVIEW OF LITERATURE

Hyoscin in the Treatment of Paralysis Agitans.—A. Rose³ reports that a woman of 69, who had suffered 5 years from paralysis agitans, came under his observation. She was constantly growing worse. He instituted treatment which consisted in the internal administration of hyoscin hydrobromate, commencing with a dose of .4 mg. ($\frac{1}{100}$ gr.) in aqueous solution twice a day. From the very first the drug appeared to have a marked effect; after 4 doses the tremor lessened in violence and after 4 days was hardly noticeable. The neuralgic pains gradually subsided, the dropsy and dyspnea disappeared and her gait became natural, though the characteristic posture remained the same. He has continued this treatment, as indicated, for the past 15 months, and the patient has very much improved during that time. At no time has he given a dose greater than .6 mg. ($\frac{1}{100}$ gr.). He believes the drug is almost a specific in this affection. [A.B.C.] [This is an old and very useful, but not a specific treatment. S.S.C.]

Application of Cold Compresses to the Chest.—C. Fernet⁴ has employed cold compresses for 15 years in various pulmonary congestions. He has found this method of treatment very useful in the pulmonary congestions of typhoid fever and of

⁶ La Semaine Médicale, December 23, 1903.

influenza; also in bronchopneumonia, whether primary or secondary, when the pneumonic areas are surrounded by congested zones; also in the peripneumonic congestion of croupous pneumonia, especially in alcoholics. He has also used cold in the treatment of acute edema of the lungs, hemoptysis of incipient tuberculosis, and in the tachycardia of infectious diseases, organic heart disease, or exophthalmic goiter. The mode of application consists in wringing a folded cloth out of cold water, laying it on the desired region for a half minute, and then replacing it by another similar compress for another half minute. Should it be desired to prolong the action of the cold, it is necessary to change the points of application, as it is the sudden impression of the cold which accomplishes the desired results. The applications may be repeated every 1 to 2 hours. [B.K.]

A New Method of Employing Adrenalin.—Mignon¹ uses an ointment of adrenalin with vaselin for local application in place of the ordinary solutions of this drug. The following formula is used:

Adrenalin 0.03 gm. ($\frac{1}{2}$ gr.)
Liquid vaselin 3 gm. (45 gr.)

To this is added:

White vaselin 12 gm. (3 dr.)
Spirit of geranium 3 drops
Lanolin 15 gm. (4 dr.)

This preparation has been successfully used in the treatment of hemorrhoids and in rhinology. Its action is a little less rapid than after the employment of a 1 to 1,000 solution, but it is more prolonged. The ointment is preferred to the solution when persistent ischemia is desired, as in acute rhinitis, recurrent congestive rhinitis with or without hydrops. In cauterization of the nasal mucous membrane, it prevents secondary congestion. In operations which may be followed by secondary hemorrhage, it is well to apply first a 1 to 1,000 solution of the drug and follow this by an application of the ointment. By its use it is sometimes possible to avoid tamponing in cases of hemorrhage. [L.F.A.]

Exercise as Related to Function.—Luther Halsey Gulick² insists that the body as a whole, and each of its parts is best exercised in accordance with its natural function. The far-reaching character of this principle is not easily seen at first glance. The upper extremity is obviously adapted for the handling of objects. The great range of movements allowed by the shoulder-joint as contrasted with the hip-joint, the structure of the forearm as compared with the leg, allowing not only flexion and extension, but pronation and supination in the arm, the more delicate structure of the hand, the independence of the phalanges, the more differentiated nerve supply to the muscular tissue—all point to a difference in function in these two organs: the lower extremity as a whole being adapted for power, the upper extremity for varied action, delicacy, quickness of movement, and the like. It is true that the upper extremity may be trained so that the weight of the body shall be handled by it alone for considerable periods. This is done by performers on the horizontal bar, the German horse, rings, and the trapeze; but it is a departure from the normal function of the arms, and results in limitation of the movements at the shoulder-joint, the stiffening of the ligaments of the hand, and general perversion of function. On the other hand, it is possible to train the legs to exercises of great skill and delicacy; jugglers who learn to handle objects with their feet while lying on their backs accomplish this. In neither case are the results worth the labor expended. They are not in line with the natural functions of the organs, and the best development of each part of the organism is related to its natural function. The physician's aim is not to see what each part can be trained to do, but to get each part into its normal condition. The body can be trained to do and to endure many things that are not only useless, but harmful. Because a man can learn to walk on his hands is not sufficient argument for men to adopt that mode of locomotion; because the shoulder-joint can be made to resemble somewhat the hip-joint is no reason why it should be

made to do so; so that, excepting conditions dependent upon pathologic states, it may be safely said as a general proposition that the exercise of the body as a whole, and of its parts in particular should be related to the natural functions.

Influence of Alcohol upon Muscular Force.—M. L. Schnyder¹ has studied the action of alcohol upon muscular energy and contraction by means of the ergograph of Dubois. The alcohol was given in the form of Bordeaux wine, which represents 16.7% of absolute alcohol. Of this, 5 ounces were given upon an empty stomach 15 minutes before work. The following conclusions are drawn: 1. Alcohol exercises a favorable action on muscular force when it is given in small quantity on an empty stomach, but only when as a result of previous physiologic conditions of the organism the reserve force of this organism is somewhat lessened. 2. This favorable action, however, remains below that of a food of the same dynamic coefficient. Furthermore, it is counteracted by the paralyzing action of alcohol on the nervous system, an action which according to the physiology of the individual is more or less pronounced, and which may be the cause of apparently contradictory results. 3. If the organism, as a result of the ingestion of other food substances, disposes of sufficient reserve force, alcohol has no longer any value as a producer of force; on the contrary, its paralyzing properties become predominant and cause a progressive diminution of the power to work. [L.F.A.]

Diuretic Action of Theophyllin.—H. Kramer³ calls attention to the diuretic action of theophyllin, which is a synthetic compound of the dimethylxanthin group. Experiments upon animals and clinical experiences have shown that its diuretic action is more powerful than that of theobromin. This action is very marked in the treatment of acute ascites. The diuretic effect is manifested soon after ingestion, and is increased for 6 hours after its absorption. If its administration is stopped, the diuresis quickly diminishes. Theophyllin does not influence the pulse-rate, arterial tension of the nervous system, but secondary nausea and vomiting are frequent. The drug is usually given in powder or in aqueous solution in the dose of from .32 gm. to 1 gm. (5 gr. to 15 gr.). [L.F.A.] [Its action clinically is marked at first, but is followed by reactionary suppression of urine. It must, therefore, be substituted by an alkaline diuretic after 2 days. S.S.C.]

Preventive Treatment of Hepatic Colic.—M. Chafford⁴ recommends sodium salicylate and sodium benzoate to prevent attacks of hepatic colic. If the kidneys are healthy he administers daily 1 gm. to 2 gm. (15 gr. to 30 gr.) of sodium salicylate with an equal quantity of sodium benzoate according to the gravity of the case and the tolerance of the patient. To this he sometimes adds 1 gm. to 2 gm. (15 gr. to 30 gr.) of Carlsbad salt. These substances are usually given in cachets at meal time. This treatment is continued for from 10 to 20 days in each month, according to the gravity, the number of crises and the duration of the remissions obtained; these remissions last, in some cases, a month, and in others over a year. Cessation of the attacks is obtained only after perseverance in this treatment. [L.F.A.]

Tincture of Iodin in the Treatment of Pulmonary Tuberculosis.—Delearde⁵ directs that patients suffering from pulmonary tuberculosis shall take a dessertspoonful of the following solution 2 times a day, immediately before the chief meals:

Tincture of iodine 20 gm. (5 dr.)
Potassium iodid 2 gm. (30 gr.)
Glycerin 40 gm. (10 dr.)
Syrup of bitter orange peel 50 gm. (12 dr.)
Water enough to make 1 liter (1 quart)

When so employed, iodine acts as a general tonic; appetite is improved, digestion facilitated, and vomiting due to coughing after meals is avoided. It also stimulates assimilation and nutrition. [L.F.A.] [Iodin is useful in cases of unmixed tuberculous infection; but not efficient when mixed infection is present. S.S.C.]

Changes in the Medical Corps of the U. S. Army for the week ended February 13, 1904:

PATTERSON, EDWIN W., contract surgeon, will proceed from Washington, D. C., to San Francisco, Cal., and report for transportation to the Philippine Islands.

BAILEY, HOWARD H., contract surgeon, leave granted November 5 is extended two months.

JORDAN, EDWARD H., contract surgeon, is granted leave for one month from January 27.

MACDONALD, CHARLES E., contract surgeon, now at Jeffersonville, N. Y., will proceed to Fort Bliss in time to arrive at that post not later than February 20, and report to the commanding officer of the Third Battalion of the Twelfth Infantry for duty with that regiment en route to the Philippine Islands.

NEWTON, RALPH W., contract surgeon, now at Barre, Vt., will proceed to Price, Utah, in time to arrive at the latter place not later than February 20, and report to the commanding officer of the companies of the Twelfth Infantry to arrive from Fort Duchesne for duty with that regiment en route to the Philippine Islands.

MILLER, WILLIAM G., contract surgeon, now at Newcastle, Pa., will proceed to Holbrook, A. T., in time to arrive at the latter place not later than February 20, and report to the commanding officer of Company F, Twelfth Infantry, for duty with that regiment en route to the Philippine Islands.

FEENEY, JOHN M., contract surgeon, is granted leave for three months, with permission to visit the United States.

CHAMBERS, WILLIAM H., contract dental surgeon, is relieved from further duty in the Department of the East and from temporary duty at Jackson Barracks, and will proceed to Atlanta, Ga., and report to the commanding general, Department of the Gulf, for assignment to duty.

CLAYTON, GEORGE R., contract surgeon, is relieved from further duty in the Philippines Division, and upon the expiration of his present leave will proceed from Kelley, Iowa, to Columbus Barracks for duty.

GRAVES, LEONARD K., contract surgeon, will proceed from New York city to Fort Douglas and report not later than February 19 to the commanding officer of the Twelfth Infantry for duty with that regiment en route to the Philippine Islands.

Changes in the Medical Corps of the U. S. Navy for the week ended February 13, 1904:

STUART, A., assistant surgeon, detached from the Naval Home, Philadelphia, Pa., and ordered to the Marietta—February 6.

BRISTER, J. M., assistant surgeon, ordered to the naval hospital, Naval Home, Philadelphia, Pa.—February 6.

WHEELER, W. M., surgeon, detached from the Nipic and ordered to the Philadelphia.

Changes in the Public Health and Marine-Hospital Service for the week ended February 11, 1904:

BROOKS, S. D., surgeon, granted leave of absence for four months from April 1, 1904, with permission to go beyond the seas.—February 6, 1904.

MAGRUDER, G. M., surgeon, granted leave of absence for two days from February 13, 1904.—February 11, 1904.

GREENE, J. B., passed assistant surgeon, granted fifteen days' extension of sick leave from February 10—February 10, 1904.

CLARK, TALIAFERRO, passed assistant surgeon, to proceed to San Juan, P. R., and assume temporary charge during the absence of the chief quarantine officer—February 9, 1904.

RICHARDSON, T. F., assistant surgeon, to report on March 9, 1904, to the chairman of the examining board at Washington, D. C., for examination to determine his fitness for promotion to the grade of passed assistant surgeon—February 9, 1904.

KING, W. W., assistant surgeon, to report on March 9, 1904, to chairman of examining board at Washington, D. C., to determine his fitness for promotion to the grade of passed assistant surgeon—February 8, 1904.

RAMUS, CARL, assistant surgeon, to report on March 9, 1904, to chairman of examining board at San Francisco, Cal., for examination to determine his fitness for promotion to the grade of passed assistant surgeon—February 9, 1904.

MOORE, DUNLOP, assistant surgeon, to report on July 25, 1904, to recorder of the examining board at Manila, P. I., for examination to determine his fitness for promotion to the grade of passed assistant surgeon—February 9, 1904.

FOX, CARROLL, assistant surgeon, to report on July 25, 1904, to the recorder of examining board at Manila, P. I., for examination to determine his fitness for promotion to the grade of passed assistant surgeon—February 9, 1904.

GOLDBERGER, JOSEPH, assistant surgeon, granted leave of absence for one month from February 10—February 10, 1904.

HOLT, J. M., assistant surgeon, to report on July 25, 1904, to recorder of examining board at Manila, P. I., for examination to determine his fitness for promotion to the grade of passed assistant surgeon—February 9, 1904.

VOGEL, C. W., assistant surgeon, to report on July 25, 1904, to recorder of examining board at Manila, P. I., for examination to determine his fitness for promotion to the grade of passed assistant surgeon—February 9, 1904.

Boards Convened.

Board convened to meet at San Francisco, Cal., for the examination of an officer of the Revenue Cutter Service, February 13, 1904. Detail for the Board: Passed Assistant Surgeon W. G. Stimpson, chairman; Assistant Surgeon Carl Ramus, recorder.

Board convened to meet at the Marine Hospital, Port Townsend, Washington, February 15, 1904, for the examination of an officer of the Revenue Cutter Service. Detail for the Board: Passed Assistant Surgeon J. H. Oakley, chairman; Passed Assistant Surgeon M. H. Foster, recorder.

Board convened to meet at the Marine Hospital, San Francisco, Cal., March 9, 1904, for the purpose of examining Assistant Surgeon Carl Ramus to determine his fitness for promotion to the grade of passed assistant surgeon. Detail for the Board: Passed Assistant Surgeon W. G. Stimpson, chairman; Passed Assistant Surgeon Rupert Blue; Passed Assistant Surgeon H. S. Cumming, recorder.

Board convened to meet at Washington, D. C., March 9, 1904, for the purpose of examining certain assistant surgeons to determine their fitness for promotion to the grade of passed assistant surgeon. Detail for the Board: Assistant Surgeon-General A. H. Glennan, Chairman; Assistant Surgeon-General G. T. Vaughan; Assistant Surgeon-General H. D. Geddings, recorder.

Board convened for the purpose of examining certain assistant surgeons to determine their fitness for promotion to the grade of passed assistant surgeon. Detail for the Board: Assistant Surgeon-General L. L. Williams, chairman; Assistant Surgeon-General W. J. Pettus; Passed Assistant Surgeon V. G. Heiser, Recorder.

PUBLISHED WEEKLY AT 1321 WALNUT STREET PHILADELPHIA BY THE AMERICAN-MEDICINE PUBLISHING COMPANY

VOL. VII, No. 9.

FEBRUARY 27, 1904.

\$5.00 YEARLY.

The adulterations of chemicals are divided by the U. S. Bureau of Chemistry into four classes: 1. The conventional, in which the changes are known, and because the public prefers them frequently for the sake of appearance. 2. The accidental. 3. The arbitrary, or such as are made in order that the product shall conform to some arbitrary standard. 4. The intentional. The second and the fourth classes are the most interesting. The greatest criticism applies to those chemicals which are allowed to be labeled as "C. P.," or "chemically pure." In strictness there is no such a substance in existence. The old-time homeopathist based his drug-giving on the two fundamental principles of the single drug, and in a high dilution or "potency," and then gave it in ordinary water, which contains 20 or 30 distinct chemicals, and in the very highest "potencies." In scientific therapeutics and chemistry the slight additions existing in all "C. P." chemicals are of little direct importance, because neither science nor chemistry admits the Hahnemannian theory of high potencies. The indirect results, however, of allowing impure drugs to be labeled "C. P." are many. The fact that there are no "C. P." drugs, absolutely speaking, makes carelessness and intentional fraud more easy. The arbitrary standard prescribing maximum and minimum limits brings about even more curious results. Opium, for instance, must not contain more than 15% of morphin. Yet it is not uncommon to find samples of powdered opium made in the ordinary way which contain more than that proportion. Dealers have to dilute it to bring it within the requirement, although this dilution itself is prohibited by most of the State laws.

Physicians as Patients' Confidants.—That physicians should be accorded the confidence of their clients—perhaps in a larger measure even than clergymen—has always been pretty generally recognized. This confidence is, indeed, freely bestowed in a good many directions, sometimes, in fact, to an entirely unnecessary extent. The physician is frequently made acquainted with internal family matters which have absolutely no bearing upon the case for the treatment of which he had been called in, and which are therefore not of a nature to exercise the slightest influence upon such treatment. In this way the physician is sometimes drawn into the position of general family father confessor. He will be

made the confidant of the husband in regard to things which should be kept a secret from the wife; the wife reveals to him things of which the husband is to know or suspect nothing; the daughter pours the little secrets of her heart into his more or less unwilling ear on the understanding that he must not under any circumstances divulge them to her parents; and the young son appeals in the strictest confidence to the doctor with regard to his sexual experience, or rather lack of experience. The picture is complete enough without the special mention of the cook and the butler. And as the medical father confessor no more than the clerical one can betray the confidence reposed in him, he is in the unenviable position of having something to conceal practically from every member of the household with regard to every other member.

"Familiarity Breeds Contempt."—While this general confidence, and consequent familiarity, lies to a certain extent in the very nature of things, it cannot by any means be likened to a bed of roses, except, perhaps, for the stings of the thorns. There can be no question that the doctor who has attained to the position of the family confidant "via medical practice," is destined to experience a gradual but unmistakable decline in the power he wields and in the reverence and recognition which his counsel once inspired. He is not spared the truth of the proverb that "familiarity breeds contempt," and he may be sure that in the event of a serious sickness the family will insist upon calling in a second, consulting physician, and *sic transit gloria mundi!* It is, however, not only the ethical part of the question that resolves itself to the disadvantage of the medical confidant, but also its consequences from a monetary point of view. The more familiar the relations become between family and physician, the less will the latter be compensated for the time and knowledge he extends, and many an overfamiliar physician has experienced, to his detriment and dismay, that the familiarity he enjoyed was the only compensation for his services that he ever received.

Presents versus Fees.—If a patient sends for a doctor because he requires his professional services, the matter amounts to a simple business transaction, and if the mutual relations do not ripen into friendship or

intimacy, the matter ends with the treatment of the case and the payment of the bill—the latter, at least, presumably. With some patients, however, it is practically impossible to confine matters to this business-like proceeding. They will abound in amiable phrases and conduct; they will probably send a small token of affection on the occasion of an addition to the physician's family; a feeling of reciprocal friendly relations will develop and strengthen by the occurrence of social family events, be they mirthful or somber; and if one of this class of patients sends at Christmas time a nice vase, an ornament, a picture or maybe a dictionary of the doctor's liking, how does the doctor stand with regard to the sending of his new year's bill? How is he to treat this patient from a business or monetary point of view? There may not have been a case of serious sickness in the family, but only say a dozen calls at the office. If he looks upon the matter from the strict business point of view and sends his bill, he runs the risk of losing his client, and if he does not send it, he loses his fees for his professional services which the client may have been perfectly willing and expecting to pay. People whose complimentary contributions to the doctor's art collection are of greater value than the expected amount of the yearly bill form a small enough minority not to require special consideration under this head.

The Disadvantages of Too Limited Confidence.

—It should not be assumed, however, that a full acquaintance with the internal family matters is in all cases harmful to the interests of the physician or superfluous for the treatment of the patient. There are many connubial relations, for instance, which both in themselves and their possible consequences upon husband or wife, or even children, may have as far reaching a psychic influence as many other more palpable causes, and the physician who is in ignorance of the real causative factors of a disease, is liable to grope in the dark and attribute certain disturbances to derangements of the body instead of the mind, in the absence of explanations to which the physician, as healer and adviser, is entitled. It is unfortunate that just such patients who are laboring under a severe mental strain will not permit the physician the slightest glimmer into their family troubles, thinking that they have done enough in describing their bodily symptoms. It is under these conditions that more confidence toward the physician should prevail, and where the physician is fully justified in endeavoring to lift the veil of the mystery. Otherwise the consequence will probably be that the physician will exhaust his knowledge as to the proper medicaments, dietary, and remedial agents, with the result that in the end the patient is no better off than at the beginning of the treatment.

The misfortune to the Johns Hopkins Hospital and Medical School by the recent Baltimore fire is a serious matter not only to those directly concerned, but to the American medical profession. We learn incidentally that the annual income of the hospital has been diminished by about \$60,000 because of the loss of the rental from 64 buildings which were destroyed. The

hospital managers are thus brought face to face with crippling economies, and a curtailment of both the practical and scientific work will be necessary unless some outside help in the emergency can be found. Baltimore is so badly stricken that she cannot help in tiding over this time of misfortune. It must be the conviction of all interested that no step backward should be taken in the great work wherein the hospital has been so able a leader. Every alumnus of the school and every friend of higher medical education should do his utmost to secure from some source the funds required to prevent the threatened calamity.

A National Government Board for the Protection of Children and Animals has been planned by the introduction of Bill No. 3,573 in the House of Representatives, and deserves the hearty support of all physicians. The protection of children and animals should be combined, because, except in rich and populous communities, if kept separate, neither would be sufficiently supported. The nature of the work is similar, and experience has shown that the work for each helps the other. Separate organizations and employes would only duplicate expense. In 8 of the 23 States and Territories west of the Mississippi, there are practically no laws for the protection of children and animals. With few exceptions, the laws in the other States are feeble and insufficient. With two exceptions, whatever effort is made to enforce such laws as do exist, is by volunteer societies. The unfortunate condition of children and animals in communities in which there is no law nor enforcement of law for their protection, must be judged from the numbers and needs of those who are relieved where law exists and is enforced. The creation of the State Board for child and animal protection in Montana is too recent for statistics of its work to be available. In Colorado, experience has shown that the protection of children and animals is quite within the power of the Board, and no child or animal is subjected to any unusual degree of abuse or neglect for more than a short time without being relieved by an officer of the Board. The Colorado State Board has one unpaid volunteer officer for every 900 of the population. This is true of the remote neighborhoods, as well as of the towns and cities. The cost of the work under this system is insignificant, being about \$5,000 per year, for an area nearly twice the size of New England, 104,000 square miles of prairie and mountain. In other States, the work of volunteer associations is almost entirely confined to the cities and towns where they exist. The activities and revenues of volunteer organizations in rich and densely populated communities may be sufficient for their needs, but in the sparsely settled States and Territories, there will long be but little law and less enforcement for the protection of children and animals, without State or National aid. The proposed law does not contemplate the enforcement of law by its own efforts, or those of its officers. It expressly forbids any supervision of or any interference with local or State organizations, which are engaged or may engage in this same kind of work. It is designed to promote and extend the formation of local organizations which will have charge in their respective fields.

Government Protection of Children.—Physicians have every day experiences which show how disease is caused, continued, or multiplied by the lack of proper care of children. This medical fact, however, needs to be kept before the minds of the community, legislators, and administrators by every means in our power. Sociologically the child's right to protection in all ways at the hands of society, the justice of his claims, the duty of recognizing this, the sentiment involved that is humanizing and uplifting, are phases of the question with which the world is daily growing more impressed. To quote Mr. Jacob Riis: "The problem of the children is the problem of the State." Abused, neglected, and defective, or delinquent children become physically, mentally, and morally defective men and women. Such men and women become criminals, paupers, lunatics, and vagabonds. They must be controlled and supported by the public. The police system, the criminal courts, the jails, reformatories, insane, and public hospitals constitute the most expensive machinery of local governments. The pauper, the tramp, the prostitute, and the gambler belong to the parasitic classes. They contribute nothing good to the community, but are a constant drain upon it. Many of them, had they been properly handled when children, might have become self-supporting and useful citizens. Only those actively engaged in this work of rescue have any conception of the number of abused and neglected children. The facts can be learned from the records of police courts, asylums, reformatories, and societies for the prevention of cruelty to children, and from the United States census reports on child labor and illiteracy. It is a subject which the general government cannot afford to neglect. The most effective ways and means of controlling these conditions will be afforded by the wise labors of a government Board for the prevention of cruelty, and for the protection of children and animals, whose "duty shall be to obtain and record information concerning the condition of dependent, neglected, and abused or viciously reared children and dumb animals throughout the United States and its possessions; to study the cause of abuse in such cases, to record the conclusions reached, to suggest and urge remedies in all such cases, to promote uniform and efficient legislation in the State, and territories, and island possessions of the United States for the protection of children and dumb animals; to secure the enforcement of law for the protection of children and dumb animals, to urge humane education of children in the public schools, to educate public sentiment concerning the rights and proper treatment of children and dumb animals, to encourage and aid the creation of State and Territorial Boards for their protection, and to whatever else will best carry out the purpose of creating this Board."

The Law as to Bakers a Health Measure.—The law limiting the hours of employment of bakers to an average of ten a day, has recently been sustained by a decision of the New York Court of Appeals. The statute was sustained as a protection of public health, and not as a labor measure. The opinion of Judge Parker was, in part, as follows:

It is reasonable to assume from the statute as a whole that the Legislature had in mind that the health and the cleanliness of health workers were of the utmost importance; that a man is more likely to be careful and cleanly when well and not overworked than when exhausted by fatigue, which makes for uncleanness and slovenly habits, and tends to dirt and disease. If there is opportunity—and who can doubt it?—for this view, then the Legislature had the power to enact as it did, and the courts are bound to sustain its action as justified by the police power. Medical authorities without number classify workers and bakers in confectioners' establishments with porters, stone cutters, and file-grinders and other workers whose occupation necessitates the inhalation of dust particles, and hence predisposes its members to tuberculosis. Medical opinion and statistics bearing upon that subject, standing alone, fully justify the section under review as one to protect the health of employees in such establishments, and it is the duty of this Court to assume that the section was framed not only in the light of, but with a full appreciation of the force of the medical authority bearing upon this subject—authority which reasonably challenges the attention of the philanthropist.

The comparative mortality in diphtheria, before and after the introduction of the antitoxin treatment, for Chicago, is given in the latest report of the commissioner:

TOTAL DIPHTHERIA DEATHS BEFORE AND DURING ANTITOXIN TREATMENT.

Before, 11,488.

During, 6,088.

Reduction in actual number of deaths, 5,400—or 47%.

AVERAGE ANNUAL POPULATION.

Before, 1,100,931.

During, 1,672,042.

DEATHS PER 10,000 OF POPULATION.

Before, 12.45.

During, 4.55.

Increase of population, 52%.

Decrease of diphtheria deaths, 63.4%.

Between October 5, 1895—the date of the first case treated—and December 31, 1903, the Antitoxin Administrators of the Department treated 7,435 cases of bacterially-verified diphtheria, of which number 479 died—a mortality rate of 6.44%. The average mortality without antitoxin still remains about 35%.

That the value of antitoxin depends upon its early administration is shown by the following:

Of the total 7,435 cases, 586 were treated on the first day of the disease, with 2 deaths—mortality rate, 0.34%.

Of 1,913 treated on the second day, 28 died—mortality rate, 1.46%.

Of 2,624 treated on the third day, 85 died—mortality rate, 3.24%.

Of 1,374 treated on the fourth day, 148 died—mortality rate, 10.8%.

Of 936 first treated later than the fourth day, 216 died—mortality rate, 23.1%.

There were included in the total 7,435 cases, 608 intubated laryngeal cases, of whom 508 recovered; mortality rate of intubated cases, 16.45%. The former mortality of this class of cases—intubated and tracheotomized—was about 85%.

There were 7,051 exposed and immunized with 500

units each; of these 46 were subsequently attacked, but all recovered. Percent of immunized subsequently attacked, 0.65.

Filth and Fraud in the Advertisements of Some Supposed Respectable Newspapers.—The ordinary sense of decency and the dictates of good commercial policy have in the vast majority of American newspaper offices proved of no use to check the shamelessness of the "medical" advertiser. The columns of the most popular papers, both of the city and country, are reeking horrors, although they are said to be "family" journals, appearing at the breakfast table for the instruction, not only of the men, but of mother, daughter, and child. And they are allowed the benefits of the United States Mail Service, although fraud and deception are rampant in them and crime is encouraged. Why will any decent person, for example, buy or allow the *New York Sun* of Sunday, February 21, to come into his house? Prominent in its columns is a most nauseating picture advertisement headed: "UNHAPPY HOMES CAUSED BY WEAKNESS IN MEN." Even in a medical journal we hesitate to repeat the disgusting parts of the advertisement about the "shrunk organs," etc., and copy only the last paragraph, which runs as follows:

The lucky discoverer simply desires to get in touch with all men who can make use of such a treatment. They should address him in confidence, Dr. H. C. Raynor, 339 Luck Building, Detroit, Mich., and immediately on receipt of your name and address it is his agreement with this paper to send you a free receipt or formula of this modern treatment by which you can cure yourself at home.

Note the words, "his agreement with this paper."

EDITORIAL ECHOES

Coffee vs. Slush.—A certain concern in this country has for some time been endeavoring, and apparently with more or less success, to create a demand for a concoction of theirs as a substitute for coffee by falsely representing in their advertisements that most of the ills of life are due to coffee. This is trash of the rankest kind. It is a species of humbuggery designed to work upon credulous minds and thereby enrich the promoters of the scheme. It is true that coffee does not agree with all persons; neither do strawberries; but that is no reason for their sweeping condemnation. To a great majority of people coffee is wholesome, invigorating, exhilarating without reaction, and indeed is almost indispensable at the breakfast table. Those who cannot use it without ill-effects should let it alone; if strawberries make you ill, shun them; if lobsters produce urticaria, don't eat them. Common sense and experience are good guides in most instances, but the course pursued by the concern alluded to, ignores experience and insults common sense—all for a cash consideration.—[*N. H. Sanitary Bulletin*, October, 1903.]

Perils of Hand Shaking.—A Belgian savant has just published a treatise on shaking hands, which he states is most dangerous, a mutual pressure of the hand being nothing more than an exchange of undesirable microbes, 80,000 of which inhabit every half-inch of the hand. The most dangerous people to shake hands with, it appears, are doctors, surgeons, nurses, hairdressers, butchers, sausage-makers, tripe merchants, tanners and leather-dressers, while the least dangerous person seems to be a worker in metal, because the metal sets up an oxidation which acts as an antiseptic. The safe course is to salute only with our heads and our hats, or always wear gloves.

AMERICAN NEWS AND NOTES.

GENERAL.

Hospital Ship Offered to Japan.—Japanese Consul-General Uchida announced recently that he had received an offer of a steamship, fully equipped as a hospital ship, from the Swedish residents of Brooklyn, the vessel to be used in caring for the sick and wounded sailors of the Japanese fleet. Mr. Uchida has taken the offer under consideration, and should it seem likely that the vessel could reach the Far East in time to be of service, she will probably be accepted.

Examination for Assistant Surgeon of the Public Health and Marine-Hospital Service.—It is announced that a board of officers will be convened to meet at the Bureau of Public Health and Marine-Hospital Service, 3 B street, S. E., Washington, D. C., Monday, April 4, 1904, at 10 o'clock a.m., for the purpose of examining candidates for admission to the grade of assistant surgeon in the Public Health and Marine-Hospital Service. Candidates must be between 22 and 30 years of age, graduates of a reputable medical college, and must furnish testimonials from responsible persons as to their professional and moral character. The tenure of office is permanent. Officers traveling under orders are allowed actual expenses. For further information, or for invitation to appear before the Board of Examiners, address Surgeon-General, Public Health and Marine-Hospital Service, Washington, D. C.

Another Victim of Eddyite Treatment.—According to the St. Louis *Post-Dispatch* of January 20, when Mrs. W. H. Davis died at the City Hospital in St. Louis recently from blood-poisoning after an illness of 6 weeks, investigation showed that when Mrs. Davis' child was born 6 weeks ago some complication arose and a woman Eddyite healer assumed charge of the case. In the meantime the condition of the patient had become alarming and a physician was called, who refused to treat the case while the Eddyite remained in charge. The faith-healer has been arrested, and she now declares that it was not the Eddyite treatment administered by her, but the hostile attitude of the patient's husband toward the treatment which is responsible for the death. She says: "He was greatly opposed to the treatment, and the hostile mind waves had the effect of thwarting everything I did toward the cure of Mrs. Davis."

Fatality of Whoopingcough.—Eliza H. Root calls attention to the fact that this disease is too little dreaded by the medical profession and that it is by no means the simple affair that many seem to suppose. From the United States census of 1900 we find that 663 died in New York from whoopingcough and 549 from scarlet fever. In Chicago 141 died from whoopingcough and 373 from scarlet fever. Philadelphia, 179 from whoopingcough, 182 from scarlet fever, and so in the different cities. Death from whoopingcough occurs most frequently from pneumonia as a complication, that induces heart failure, or a bronchitis may occur that ends in suffocation. Asphyxia, or marasmus, due to the continued ejecting of the food or loss of appetite, may cause death. Cerebral apoplexy, external hemorrhage and emphysema of the subcutaneous tissues after rupture of the larynx is occasionally given as the cause of death. Even when death does not occur, severe disturbances of the nervous system may remain, as weakness of the intellect and memory, imbecility, hemiplegia, with consequent chorea, epilepsy, etc. Visual defects, strabismus, blindness and deafness, partial or complete, and even deafmutism may remain. Whoopingcough, it is evident, should be under the control of health authorities, subject to quarantine and other preventive measures as much as scarlet fever.—[*Woman's Medical Journal*.]

Miscellaneous.—NEW YORK: A dinner will be given at Delmonico's, Tuesday evening, March 1, 1904, at 7 o'clock, to Dr. D. B. St. John Roosa, which is to commemorate the twenty-first anniversary since the inauguration of postgraduate medical instruction in this country. Dr. William Osler, of Baltimore, will preside.—PHILADELPHIA: The new medical laboratories of the University of Pennsylvania will be dedicated next June, and the medical department will move into its new quarters during the summer.—SOUTH SHAFESBURY, VT.: According to newspaper accounts, the oldest person in Vermont, and possibly the oldest in New England, Mrs. Honora McCarthy, of this town, is preparing to celebrate her 114th birthday.—BOSTON: Dr. Fritz Walter Gay, of Malden, was appointed pathologist at the Malden Hospital by the executive committee at a meeting held recently.—WASHINGTON: Dr. Anita Newcomb McGee, prominently identified with the American hospital service during the Spanish war, will take to Japan a corps of trained nurses for hospital service with the Japanese Army.—FOREIGN: Dr. Lilius Hamilton, one of the first English women to take her medical degree, afterward became famous by her appointment as medical adviser to the Ameer of Afghanistan, to whose court she went, principally to teach the ladies how to wear European dress. Dr. Hamilton has now given up medicine for the time being and has emigrated to South Africa, where she intends to rear mules on a large scale.

Sanitary Problems in Connection with the Isthmian Canal.—A commission of the United States will employ one of the most distinguished sanitary engineers in the United States, and, probably in conjunction with the Marine-Hospital and Public Health Service, will institute a comprehensive system of keeping the Panama region free from pestilence. It is pointed out that with a low-class laboring population summoned from other tropical countries, conditions would be ripe for such an intermixture of infections as would be extremely dangerous. With all the ships plying between those ports during the construction period and our own coast cities it is felt that the danger of transmitting tropical diseases would be very great, and therefore on our own account quite as much as out of consideration for the health of the Isthmus, the most radical measures of sanitation will be adopted and enforced.

Will Abolish the Office of Coroner.—The Philadelphia *Ledger*, commenting on the proposition to abolish the office of coroner in New York, says: A bill has been prepared, under the auspices of the leading medical societies of New York, abolishing the time-honored coroner's office, and substituting an official examination by physicians, who will determine the cause of sudden or suspicious deaths from the medical point of view alone. The medical board will not undertake to fix the criminal responsibility for the death. That investigation will be conducted by the District Attorney. The coroner's jury will be abolished with the coroner's office. The new system will go into operation on January 1, 1905. Massachusetts has a similar system. Inasmuch as the States are disposed to adopt legislation that has proved to be satisfactory in practical operation, it is probable that the coroner's office will be abolished eventually throughout the country. It is confidently predicted that the New York bill will be passed. The old system is antiquated, burdensome, and enormously expensive in New York City.

Proof Conclusive in Favor of Vaccination.—A New York exchange says C. E. A. Winslow, in an admirable survey of the statistical data in favor of the efficacy of vaccination, points out that a single vaccination greatly reduces the probability of an attack of smallpox, postpones it to a later period of life, and renders it less dangerous if it does ensue. To insure absolute protection, revaccination is required. During the smallpox epidemic of 1871, of 738 nurses and attendants in the Metropolitan Asylum Board Hospital, 79 were survivors from smallpox attack, and escaped infection; 645 were revaccinated on entrance, and all escaped; 10 were not revaccinated and all took smallpox. Mr. Winslow says if statistics ever proved anything, those quoted prove the protective influence of vaccination. If any fact in science is certain, it is that a successful vaccination absolutely prevents smallpox for a period of from 7 to 10 years, that after that period it renders the disease less fatal, and that its complete protective effect may be renewed by revaccination.

EASTERN STATES.

Crippled and Deformed Children in Massachusetts.—There was recently received the report of the State Board of Charity, in accordance with the resolve passed by the last Legislature requiring the board to ascertain the number of crippled and deformed children in the State, who, because of their physical condition, could not attend the public schools. The board reports that of 353 towns and cities, 36 made no reply to the inquiry; 251 had no children of the class mentioned, and 65 reported 208. The board deduces that including the cities and towns making no report, the number would reach 250. The board is of the opinion that if a rigid investigation were made the number would be largely increased.

NEW YORK.

No Saliva on Transfer Slips.—Transfer agents and conductors of the New York City Street Railway Company are worrying over orders issued recently to the effect that when they issue transfer slips to a passenger they must not wet the slips with the thumb or finger. The slips are of thin paper and bound so closely that to hurry the process of issuing transfers the conductors used to wet their thumbs with their tongues in order to remove the slips quickly.

Watertown's Typhoid Epidemic Shows no Abatement.—Information under date of February 19 says: A preliminary report on the typhoid fever epidemic at Watertown, where there have been 300 cases of the disease since January 1, has been made to the State Health Department by Professor O. H. Landreth, who is making an investigation of the situation. The epidemic, according to advices received by the department, is still raging with unabated vigor, 5 or 6 new cases being reported daily.

Medical Legislation in New York State.—The licensed medical practitioners of the State are understood to be behind bills which have been introduced in the Legislature to prevent opticians from prescribing glasses for defective eyes, and to prevent any newspaper, periodical, except a surgical magazine or periodical from printing any picture of a man, woman or child, or any part or parts of the human body in connection with the advertisement of patent medicines. The latter bill

makes a violation of its provision punishable by a fine of \$25 for each offense.

Scope of Eye and Ear Infirmary to be Curtailed.—Action was taken recently by the board of directors of the New York Ear and Eye Infirmary whereby the scope of that institution will be narrowed after March 1, and may be even further curtailed after May 1, in the event that funds for the hospital's maintenance are not forthcoming. This decision was reached after a long session. The institution has an endowment, but not sufficient for the needs of its work. The interest on the total assets amounts to about \$17,000 per annum, and as the voluntary contributions were declared yesterday to be not more than \$1,200 a year, the expense of operating the pavilions is far in excess of the income.

Polluted Water Causes Watertown's Typhoid Epidemic.—Professor O. H. Landreth, of the State Department of Health, has made his preliminary report relative to Watertown's typhoid epidemic, in which he says that the city's water supply is the most probable cause. The water is obtained from the Black river, into which numerous villages drain. In this territory above the city there were a number of cases of typhoid some months ago, and Professor Landreth believes that there was an accumulation of polluting material on the watershed, which was washed down the stream during the thaw in the latter part of December. Watertown is constructing a sand filtration plant, but it will be some months before it is completed. Meantime, the State Department of Health has warned the people of the city to boil all the water they use.

Physicians Undergoing Examination.—Information from Albany, under date of February 13, says: The subjection of 5 candidates for appointment to the post of superintendent of the new State Hospital for the treatment of the tuberculous to an actual test of their ability to deal with tuberculosis, is a phase of a State civil examination which is in progress in this city. Five patients were subjected to an examination, each of the candidates being required to diagnose the condition of each patient. To test the ability of the candidates, one man, suffering from another disease, but of the general appearance of tuberculosis was included as a subject in the examination. Of course the result of the test is not divulged, as the examination is still in progress. The hospital, which will be ready for occupancy soon, is located at Raybrook, in the Adirondacks.

Child Labor in New York State.—Child labor is rapidly declining in New York State. Not only has there been a large decrease in the total number of children receiving permits to work, but there has been, also, almost a total elimination of the perjury resorted to by parents, under the old law, to get children into factories and stores. The establishment of systematic cooperation between the authorities who enforce the law and the authorities who investigate, and if necessary, relieve the poverty conditions so often alleged as the cause of child labor is reported by the Child Labor Committee just issued. The new law has been in operation since October 1. During October, November, and December, certificates were issued in this city to 2,922 children, or 67% of all who applied, whereas during the same months of the preceding year certificates were issued to 4,353 children, or 80% of all who applied. The stricter requirements which have caused this change are a minimum age, a minimum amount of schooling and proof that the child has been observing the Compulsory School law.

Report from Juvenile Court in New York.—The first annual report of the Juvenile Court in New York City has been issued. One of the interesting features is the comparatively small number of girl offenders. Out of 4,790 children under 16 years convicted by the magistrates, 4,360 were boys, while only 430 were girls. Against this showing for the girls is their tendency, according to the report, to commit suicide at fancied grievances. Six girls were arraigned on this charge. Each of them asserted that her parents had failed to care for her. No boys were brought to court on this charge. The report shows that the children arrested numbered 7,647. The number of girls acquitted was 1,564, and only 243 boys were acquitted. A comparison of the ages of the children with the number of arrests shows that the greatest number of arrests were made among children between 14 and 16 years of age. Only 148 of the total of 1,117 paroled were committed for violation of the parole. This shows more than 87% of the total of parole cases successful.

PHILADELPHIA, PENNSYLVANIA, ETC.

Bogus Death Certificates.—Two arrests have been made as the result of an investigation instituted by Coroner Dugan into an alleged conspiracy to furnish fraudulent death certificates.

Medical Examiners Resign.—Drs. J. H. Musser and J. Chalmers Da Costa who, at Mayor Weaver's request, served as the Medical Civil Service Examining Board in connection with the examination of candidates for the medical inspectorships in the Department of Health, sent their resignations to the mayor recently. Lack of time to attend to these duties was the cause assigned in each case.

Medical Inspectors Appointed.—Forty medical inspectors have been recently appointed by the Health Department of Philadelphia, pursuant to a recent act passed by the City Council. These medical inspectors are to give their entire time to the city, and each is placed in charge of a certain district. It is his duty to report all cases of infectious diseases, to trace the source of epidemics, to report any unhygienic conditions, to inspect public schools, etc. Each inspector is to receive a salary of \$1,200 per annum.

The Fight against Tuberculosis.—The Pennsylvania Society for the Prevention of Tuberculosis has determined to begin an active campaign for the prevention of the spread of tuberculosis, as well as other infectious diseases. The measures proposed include the cleaning of the streets only between midnight and 5 or 6 o'clock in the morning; the thorough wetting of the streets before such cleaning, the heating of all trolley cars in cold weather, the withdrawal of all trolley cars with upholstered seats, the better cleaning of street cars and the enforcement of the antisputting street car ordinance.

WESTERN STATES.

Diphtheria and Typhoid Reported in Minneapolis.—According to newspaper accounts, if the epidemics of diphtheria and typhoid continue, the State university will close for the balance of the year. For the third time President Northrop publicly warned the student body against city water. A serious epidemic is feared.

Chicago Hospitals Overcrowded.—According to newspaper reports, nearly every hospital in the city has one or more cases of pneumonia, while the less serious diseases are even more prevalent. Added to these are the far greater number of cases treated at homes, making the list of sufferers a long one. The situation is complicated by the fact that nearly every one of Chicago's big hospitals is filled, and unable to take any more patients. At the County Hospital there are 949 patients, leaving but one vacant bed. Conditions are similar in the other large hospitals. Of the 661 deaths reported last week by the Health department report, 175 were from pneumonia, while 37 were from cases of bronchitis and influenza.

Would Stop Overcrowding of Cars in Cleveland.—Information from Cleveland, Ohio, under date of February 5, says: The overcrowding of street cars has become such an annoyance in Cleveland that the Board of Health at its next meeting in March will take vigorous steps to put an end to it. At that meeting a resolution will be adopted making it a violation of the law to overcrowd the cars. The limit will be the number that can be seated and a reasonable number standing, but no crowding will be permitted. The Board of Health claims the conditions that prevail in Cleveland cars at certain periods of the day are a menace to health, and Mayor Johnson and the city Law Department declare that the Board has power to regulate the condition of the cars, just the same as it can regulate the sanitation of public buildings.

Deaths and Disease in Indiana in January.—The January Bulletin of the State Board of Health says: There were reported 3,177 deaths in Indiana in January, a rate of 14.8. In the corresponding month last year there were 2,910 deaths, rate 13.2. Cities and country: The city rate was 18.8, and the country 12.8. Seventeen percent of city deaths were under 1 year of age, and 15.9% in the country. For old people, however, the rates were country, 34.3%; and cities 26.5%. Tonsillitis was the most prevalent disease, and measles the next most prevalent. Pneumonia was bad, and it stands fourth, and caused 540 deaths. The dreaded cerebrospinal meningitis was the least prevalent. The reports show more typhoid fever than is usual in January. A complete sum-up makes plain the fact that the public health this January was not so good as the same month last year.

Inspection of School Children in Chicago.—It is proposed in Chicago to thoroughly inspect the school children in each of the city schools. Teachers and principals must report for medical examination any pupils they believe physically defective, deformed, or afflicted with a functional disorder. The rules provide that the examinations shall be made by a school medical inspector in the office of the principal and under the latter's supervision. These examinations are limited to the following subjects: Eyes—Diseases of the conjunctiva and lacrimal apparatus, muscles of the eyeball, visual acuity, hypermetropia, myopia, astigmatism. Ears—External ear, auditory meatus, drum membrane, hearing, acute or chronic diseases of middle ear. Mouth and Pharynx—Defects of tongue, lips, palate, condition of teeth, hypertrophy of tonsils, pharyngitis, adenoids, granulations, etc. Nose—Acute or chronic rhinitis, nasal hypertrophies, polypus, deflection of septum, etc. Chest—Abnormal development, round shoulders, spinal deflection, diseases of the heart and lungs. Skin—Acute or chronic affections, scabies, pediculosis, favus, etc. General Nutritional and Structural Disorders—Anemia, chronic headaches, glandular enlargement, tuberculosis, deficiency of muscular development, nervousness, chorea, or any pathologic condition which may retard the pupil's growth or influence his progress in

school work. It is provided that no examinations will be made which require the pupils to undress, except in special cases, for which the inspecting physician must secure the written consent of the parent or guardian.

FOREIGN NEWS AND NOTES

GENERAL.

The New German Child Labor Law.—The provisions of the law, which went into effect at the beginning of the year, are so arranged as to absolutely prohibit the labor of children in many heavy vocations, such as building operations, brick yards, etc., and to admit of their employment in factories under 14 years, certain restrictions and safeguards being observed. Owing to the prevalence of diverse home industries, conducted outside of factories, the great majority of German child laborers, more than a half million in all, are engaged in the homes, only 27,000 under 14 being employed in factory plants. It is owing to this fact that the German law draws distinction between nonrelated and related children, the protection extended to the former being considerably greater than to the latter.—[*Boston Transcript*.]

Leprosy in Colombia, South America.—Minister Beaupré reports from Bogota, November 5, as follows: One of the gravest questions now confronting Colombia is the terrible one of leprosy. This awful disease has invaded the country to an alarming extent, and extraordinary measures have become necessary to check its spread. He incloses a copy and translation of a law enacted by Congress, under which lazarettes are to be established in each Department of the Republic, in which all the lepers are to be confined. Various other provisions are made, but the central idea is to isolate all those who are suffering from the malady. For the Department of Antioquia a lazaretto is already operated at an expense of more than 3,000,000 pesos, and much other good work has been done in various sections by private efforts and subscriptions. The stipulations and appropriations of this new law will encourage further efforts on the part of societies and individuals.

Medical School Inspection Abroad.—An exchange says: The foreign custom, universal in France and Germany, of insisting upon each child entering school, and at regular intervals thereafter, submitting to a medical examination, is an example worthy of emulation in vaunted up-to-date communities. The question of vaccination and the control of contagious epidemic are the only occasions when medical intervention is usual in the schools in this country. Abroad it is customary to appoint school physicians, whose duty it is to examine twice a year all the pupils with reference to the senses, the spinal column, the development of the limbs, and to make recommendations for their special instruction on account of stuttering, etc. Not their least important work is the quarterly or in some cities semimonthly sanitary inspection of school rooms and buildings. It is one of the duties of teachers to call the attention of the school physician to any pupils whose state of health during the interval since the previous visit creates suspicion. The physician can, however, in case of sick pupils, only notify the parents formally of the child's condition, their treatment being left entirely in the hands of the family physician. It is proposed by the French medical fraternity to have the school physician's duties extended to an inspection of the condition of the dwellings of sick school children, and also to give advice concerning the architecture of schools and the division of school hours.

Arsenic in Food.—A recent epidemic of arsenic poisoning occurred in Manchester, England, which was thought to be due to contaminated beer. A government commission was appointed to investigate the condition. After showing that the arsenic got into the beer from the impure sulfuric acid used in the manufacture of brewing sugar or glucose, the commission, under the chairmanship of Lord Kelvin, continued their inquiries, which had convinced them that poisoning by arsenic contained in matters of common use was by no means confined to this one case. Says the *Hospital*, in a note of this report: "The magnitude of the whole question is shown by the statement that what was called the Manchester epidemic was known to have affected 6,000 persons, and was believed to have affected many more; while the ascertained deaths were over 100, leaving an indefinite number registered as from various causes, but as to which the influence of arsenic could be reasonably suspected. Perhaps the most remarkable result of the inquiry was the discovery that, although the bulk of cases in the Manchester epidemic was clearly due to contaminated sugar, yet illness of a similar kind had prevailed extensively in various localities in which contaminated sugar had not been used by brewers, and that when its arsenical character was no longer in doubt, it was without much difficulty traced to the contamination of malt by the use of arsenical gas coke in the drying kilns. Certain samples of such malt contained as much as $\frac{1}{10}$ gr. of arsenic to the pound, and beer brewed from malt prepared in a similar manner was found to contain $\frac{1}{10}$ gr. of arsenic to the gallon. After fully discussing the questions

hence arising, the report goes on to enumerate other methods by which arsenic may be introduced into common forms of food, and the list of foods liable to be affected includes beer, golden syrup and treacle, foods containing glucose, vinegar, Demarara sugar, various extracts of malt, manufactured either for sale to invalids or for use by bakers, 'prepared' and 'infant' foods under a variety of names, yeast cakes, and foods to which certain coloring matters or preservatives have been added."

OBITUARIES.

William F. Buchanan, at his home in Philadelphia, February 16. A graduate of the University of Pennsylvania. He was U. S. Army surgeon during the Civil war. He was attached to the 68th Illinois Volunteers until 1864, when he was appointed assistant surgeon and later made assistant medical director in the department of the South. Later he was stationed successively at Fort Leavenworth, Denver, Lexington, Mo., and Fort Harker, Kansas. He was with General Hancock in his Indian expedition in the West.

Evan W. Warfield, at his home in Longwood, Md., February 17, aged 79. Dr. Warfield was one of the oldest and best known physicians in his part of the State; a descendant of Revolutionary stock. He had practised in Howard and surrounding counties for over 50 years, being a graduate of the University of Maryland at the age of 19.

John Eggleston Byers, at his home in Butler, Pa., February 8, of cerebral hemorrhage, at the age of 49; a graduate of the New York University in 1879; surgeon to the Pennsylvania railroad; a member of various societies, including the National Association of Railway Surgeons.

Gustavus Liebmann, at his residence in Brookline, February 21. He was born in Wurtemberg 71 years ago, and received his physician's degree at the University of Tübingen, coming to America when he was about 25 years old. For 20 years he practised medicine in Baltimore.

K. C. C. Hill, at Monterey, Mex., February 13, aged 76. He joined the U. S. Army in the War with Mexico, being at that time only 14 years of age; he was captured and later adopted by Santa Ana by whom he was educated and made a member of his official family.

Henry L. Smith, at his home in Hudson, N. Y., February 11, aged 60; a graduate of the College of Physicians and Surgeons of New York in 1864; member of the New York State Medical Association and of the New York State and Columbia County Societies.

Virgil O. Haddon, at his home in Atlanta, from pneumonia, February 7, aged 54; a graduate of Bellevue Medical College, N. Y., in 1874; professor of obstetrics and diseases of women and children of the Atlanta College of Physicians and Surgeons.

R. C. Downey, at his home in Middleton, Conn., February 15, of erysipelas, aged 35; a graduate of the University of Vermont and of Bellevue Medical College; a member of the State Medical Society and the Central Medical Association.

Henry Martin Dearborn, at his home in New York, February 16, from pneumonia. He was an expert dermatologist and connected with numerous hospitals and societies; a graduate of Bowdoin Medical College, in 1879.

M. Luther Goodlet, at his home in Tupelo, Miss., February 5, aged 69; a graduate of the Medical College of the State of South Carolina, Charleston, in 1861; surgeon in the Southern army during the Civil war.

Robert Lantenbach, at his home in Baltimore, February 16, aged 69; a graduate of the Medical Department of the University of Maryland and an army surgeon during the Civil war.

Edward Howard Moore, at the Lawrence Hospital, Columbus, Ohio, February 6, of meningitis, aged 28; a graduate of the Starling Medical College, Columbus, in 1903.

Richard McDermott, at his home in Thompson, Mich., February 4, aged 53; a graduate of the Starling Medical College, Columbus, in 1882.

Charles H. St. John, at his home in Salina, Kan., February 5; a graduate of the Homeopathic Medical College, Kansas City, Mo., in 1896.

Edward C. Runge, at his home in St. Louis, February 10, of pneumonia, aged 50; graduate of the Washington University, St. Louis, in 1891.

Alvan R. Davis, a native of Dover, Del., February 16, at Rawlins, Wyo. He was a graduate of Jefferson Medical College, Philadelphia.

John E. Hickson, at his home in Blissville, Long Island City, February 6, aged 48; a graduate of Bellevue Medical College in 1889.

Charles F. Alsentzer, at his home in Philadelphia, February 16, aged 38. A graduate of the University of Pennsylvania in 1883.

Theodore F. Stark, at his home in Minneapolis, Minn., January 30; a graduate of Jefferson Medical College, Philadelphia, in 1877.

Nicholas M. Edward, at his home in Slater, Mo., February 8, aged 66; a graduate of the University of Pennsylvania in 1890.

John W. Jones, at his home in Tarboro, N. C., January 28, aged 72; a graduate of the University of Pennsylvania in 1857.

CLINICAL NOTES AND CORRESPONDENCE

[Communications are invited for this Department. The Editor is not responsible for the views advanced by any contributor.]

AN APPEAL TO GENERAL PRACTITIONERS AND TO OBSTETRICIANS.

BY

CHARLES SEDGWICK MINOT, M.D.,

of Boston, Mass.

Harvard Embryological Laboratory.

To the Editor of American Medicine:—The opportunity which you afford me of calling attention to the needs of the Harvard embryologic collection is welcome and timely. This collection, planned 10 years ago with the utmost systematic care, is now, in many parts, approaching completion. It was proposed to illustrate, by graded series of sections, the development of typical vertebrates from fishes to man inclusive. Seven hundred embryos have already been placed in the cabinets. The technical skill acquired in preparing this large number of specimens is such that an embryo is ordinarily cut into several hundred sections without the loss of a single one, and these are arranged on the slides with the precision of set type. Every one of the sections is so numbered as to permit ready reference.

The fishes chosen, and well represented, comprise the trout from State hatcheries, ganoids from the West, and torpedoes from Italy. The amphibians include both the large western and small eastern salamanders, and frogs. The reptiles are European lizards. Very complete series of rabbits, cats, and pigs have furnished mammalian material. Scientists working in the laboratory with the cooperation of those in distant places, have collected these specimens at great expense of time and effort. It is obvious, however, that human embryos cannot be gathered by embryologists. For such specimens, so desirable from the zoological standpoint, and indispensable for a medical school, all must depend upon practitioners.

The embryos desired are those of the first 3 months, including all which are less than 3 inches in length. To be of value they should be placed as soon as possible, and without handling, in a 10% solution of formalin. This is made by adding 10 parts of formalin to 90 parts of water, and may be obtained of any apothecary. Since one can never foretell when such a rare treasure as a normal young human embryo is to be at his disposal, a tightly closed jar of this preservative should be kept always at hand. The laboratory is ready to pay the expense of preserving and forwarding specimens, and will duly acknowledge the receipt of embryos. The lack of human specimens is keenly felt, and this appeal for them is urgent.

Finally, it should be said that the Harvard embryologic collection is for the use of investigators, whether they are stationed at this medical school or not. It has already been used by scientists visiting Boston for this purpose; and it is open to the inspection of any physician who may be interested in its development.

DESCRIPTION OF METHOD OF PREPARING BRAINS USED IN CLASS DEMONSTRATION.¹

BY

ADDINELL HEWSON, A.M., M.D.,

of Philadelphia.

Assistant Professor and Demonstrator of Anatomy, Jefferson Medical College; Professor of Anatomy, Philadelphia Polyclinic College for Graduates in Medicine.

In presenting a paper of this sort it is necessary to explain the character of material at my disposal. This material comes from all parts of Pennsylvania, and preservation of the body is made therefore in various stages of decomposition, varying with the season of the year. The bodies are received not less than 2 days after death, and in many instances 6, 7, and even 10 days after death.

¹ Read before the Association of American Anatomists, at Philadelphia, December 29, 1903.

The origin of this solution was reached after experimentation by me with Wickersheimer's solution and the results obtained by the Kaiserling solution. The objection to both of these being that to prepare the body in bulk, either 2 injections were required as in the former or 2 immersions of isolated parts or organs in the latter. The object I had in view was to obtain results which combined the good points of each. The flexibility of bodies injected by Wickersheimer's solution and the nonstability of color obtained in Kaiserling, except when kept in the dark, were 2 points I endeavored to obtain as a permanency, together with the maintenance of the nervous system in a condition to allow the frequent handling for class demonstration:

Sodium arseniate	2 kilos.
Potassium nitrate.....	1 kilo.
Glycerin	2,000 cc.
Water.....	7,700 cc.
Formaldehyd (40% solution).....	150 cc.
Carbolic acid (No. 1 delq. crystals).....	150 cc.

This solution is made by boiling the potassium nitrate, sodium arseniate, carbolic acid and water until the salts are completely dissolved and when cold the addition of the glycerin and formaldehyd and a small quantity of thymol, sufficient to saturate; as this latter is not very soluble in water (1-2,000) only a small quantity is necessary; a piece about the size of the end of the thumb is sufficient for a carboy of solution.

The bodies are injected either from the carotid or from the femoral by pressure of 8 to 10 pounds or by elevation of a tank containing the fluid, 10 to 12 feet. The best injections are made by washing out the vascular system with 2 quarts of normal salt solution immediately preceding the preservative fluid, care being taken either to open the deep jugular or femoral vein. This washes out the fluid retained in the venous system, but has the effect of slightly blanching the color of the muscles; it also permits the distending venous injection to flow more freely.

The quantity of preserving fluid must vary with the weight and size of the individual subject, rarely less in the adult than 2 gallons and often as much as 3½ to 4 gallons in larger subjects being required.

The effect of this injection on an adult body is to preserve the cuticle intact, giving the skin firmness with pliability; the fatty subcutaneous tissue appears in its normal condition, the fibrous tissues of the body are not hardened and the muscles appear with their normal colorings, the arteries when atheromatous are made slightly more elastic and the nerves a little denser and very easily distinguished. The viscera keep their normal position and shape, this is instanced by the spleen retaining its 3 surfaces with the complete arrest of decomposition at the time of injection. This is so complete that I have no hesitation in using the injection in bodies infested with maggots. This solution does not affect the flexibility of the joints or of the body in any way as the joints and muscles are not in any instance rendered rigid.

In regard to the effect of injection upon the preparation of bones I have found that if the part is boiled, a darker condition of the bone is found, but that if the bone is allowed to macerate in water at a temperature of about 100° F., it assumes a slightly yellowish tinge.

The arterial distending injection is used 24 to 36 hours after the preservative injection made of starch, colored with light English vermilion. The venous injection is made with the same starch, colored with ultramarine blue.

I have found in making röntgen ray pictures that it is possible with this arterial solution to get perfect views of the anastomosis about the larger joints, and if the venous injection is also desired by substituting 2 oz. of bismuth subnitrate for the ultramarine blue to the same starch solution, the veins can also be distinguished on the röntgen ray plate. The presence of the arsenic in the tissues interferes somewhat with the penetration of the röntgen rays, and an increased exposure is necessary about the denser parts of the bodies (shoulder-joint, hip-joint).

In the brains here presented, the bodies after being subjected to the foregoing process, were placed in cold storage and allowed to remain six or eight months until the requirements of the class demanded their use. One of these brains was not

taken out until the close of the 6 weeks' period devoted to dissection, and was found in very good condition. As a rule, however, I prefer to remove the brain as soon as the superficies of the head have been dissected; the calvaria is removed; the dura severed in the same incision, and the brain removed from the skull with the pia and arachnoid in place. It is then placed in the solution minus the glycerin, with the addition of 5% formaldehyd. It is allowed to remain in this solution from 24, 36 to 48 hours, according to the softness of the brain; at the end of this time 5% more of formaldehyd is added, and the whole is stored away in individual jars (pressed glass meat jars, Pittsburg Glass Manufacturing Co.) in the dark.

The object obtained by placing the brain in the modified solution with 5% formaldehyd added is to harden the central portion as well as the superficial parts, the membranes being in situ, the addition of 5% more, making the solution plus 10% of formaldehyd, hardens the brain and with the pia and arachnoid still in contact fixes the structures in their normal position. If, however, the pia and arachnoid are removed it is best to store the brain only in the original solution minus the glycerin but plus 2.5% formaldehyd. The effect produced by these solutions is as follows:

The complete arrest of decomposition, shown in several brains where 1 part has been entirely disintegrated at the time of the original injection of the body. The elastic condition of the brain permitting handling which could not be undertaken otherwise. The darkening of the gray matter and all of the ganglions, thereby permitting an exhibition which is difficult to find in the ordinary brain injected by other solutions. The specific gravity of the original solution is 1,260. It is acid in reaction. The specific gravity of storing solution is 1,252, which floats the brain without the addition of cotton to support it.

I have used this injection in fetal subjects and find that if the body is merely injected it does not harden, but after the body is injected and is immersed in a similar injection it is very apt to become hard and somewhat stiff. I would therefore advise that for fetal subjects not more than .5% of formaldehyd be used in the preparation of fetal brains after they are removed and in the original injection.

NEGLECTED TEETH A CAUSE OF DISEASES OF THE STOMACH.

BY

ERWIN H. TAYLOR, M.D.,
of Pittsfield, Mass.

As a result of our modern manner of living with its many luxuries, and owing to our negligence, we are paying the penalty of the violation of the laws of nature by our decaying teeth, indigestion, and the thousand and one disturbances of body and mind which follow impaired digestion and nutrition. Indigestion has become so frequent in America that some of our friends across the water have gone so far as to call it americanitis.

When we stop to consider the way in which we Americans live, it is not surprising. The American is a hustler at the expense of his stomach. Let us take the average American business man as an example. He arises in the morning and hastily eats a hearty breakfast composed of such articles as hot pancakes, fried potatoes, hard boiled eggs or sausage. Instead of masticating the food until it is well ground up and lubricated with the saliva, he washes the large masses of half masticated food down with several cups of strong coffee in order that he may save time. Then, instead of cleansing his teeth as he should, he hurries away to his place of business chewing a tooth-pick. At noon he rushes up to a quick-lunch counter and utilizes 2 or 3 cups of tea to wash down a few sandwiches and a piece of mince pie. Is it any wonder that the teeth decay, and that the stomach rebels?

There are many factors which enter into the causation of diseases of the stomach, but in this brief article I wish to call attention to the importance of the preservation and care of the teeth as an essential feature in the maintenance of good digestion.

The more I learn concerning the complex changes that take place in the process of digestion, the more am I impressed with the supreme importance of having the food properly prepared in the mouth for its reception by the gastrointestinal tract.

Comparatively few people reach the age of 25 without a few and often many defects in their teeth. Quite often, even at this early age, the individual may have lost all his natural teeth. Many people never think of a dentist till nature gives them a gentle reminder in the form of a toothache. Then they blame nature for giving them such poor teeth, and insist on having the offending member extracted by way of revenge, totally ignoring its value to the preservation of health if it were properly repaired. When this policy is pursued, one tooth after another is sacrificed until there are not enough left to chew the food. Now the only way that the patient can better his condition and have the mouth look presentable is by artificial teeth, which can rarely prove as satisfactory as well-preserved natural teeth.

Good teeth give beauty and expression to the face and are important aids in the production of speech as well as in mastication. Patients should be instructed concerning the value of these important structures and how to take better care of them. When the mouth is neglected, food accumulates on and between the teeth, thus furnishing the most favorable conditions for the growth and development of microorganisms, since we have heat, moisture, and plenty of pabulum. Microorganisms are always present in the mouth, a fact which is not difficult to believe if one will take the trouble to place a drop of saliva under the microscope. The saliva, taken from the neglected mouth with decayed teeth, will be literally swarming with microorganisms, while the saliva from a mouth well taken care of, with sound teeth, will be found to contain comparatively few germs.

When the food is allowed to accumulate and remain between the teeth, these microorganisms multiply rapidly and give rise to fermentation and putrefaction. As a result of the action of these germs and their products, we have various pathologic changes produced in the mouth and teeth, among which is dental caries.

According to Miller, the fermentation is the result of the action of these microorganisms on the sugar taken into the mouth, either as such or as starch, this latter being converted into sugar by the ptyalin of the saliva. The germs act on the sugar and change it into acids, chief among which is lactic acid. This acid now coming in contact with the tooth, dissolves the inorganic salts, exposing the organic elements of the tooth, which are decomposed by the peptonizing bacteria that are present. Over 22 kinds of germs have been found to take a more or less active part in the production of dental caries.

Many bacteria have the power of multiplying very rapidly. Under the most favorable conditions a single bacterium may divide as often as once in 20 minutes. At this rate a single bacterium, at the end of 12 hours, may have more than 16,000,000 descendants, or in 24 hours more than 280,000,000,000. Although bacteria do not ordinarily multiply as rapidly as this, it gives us some idea of their possibilities when the conditions are favorable.

Patients with dental caries are seldom perfectly healthy. During the process of putrefaction of nitrogenous matter, poisonous decomposition products are produced. These germs and their poisonous products produce irritation and inflammation of the mucous membrane of the mouth. Pyorrhea alveolaris and inflammation of the pulp may also be caused by these microorganisms. The saliva containing these microorganisms and their poisonous products is swallowed and the germs go on developing and continue to elaborate their poisons which produce irritation and hyperemia of the mucous membrane of the stomach. If this process is long continued there is more or less thickening of the mucous membrane of the stomach and derangement of the gastric secretion. Instead of the normal secretion of gastric juice, there is a heavy, ropy, tenacious mucus which completely covers the mucous membrane and obstructs the mouths of the glands. This prevents the gastric juice from penetrating and mixing with the food as well as normally. The food remains longer in the stomach and

the normal digestive process yields to one of fermentation and putrefaction, the products of which produce not only local disturbance, but are absorbed from the stomach and bowels and cause constitutional changes and symptoms more or less severe.

Patients with neglected teeth and caries are also generally negligent about properly masticating their food. They are not satisfied to chew the food until it is well ground up and sufficiently well lubricated with the saliva to render the act of swallowing easy as nature intended, but seek for a quicker way by washing large masses of poorly masticated food down into the stomach with various beverages. It is difficult for the gastric juice to penetrate and digest these large morsels of food and they remain in the stomach longer and predispose to fermentation and putrefaction. The food passes on into the bowel in a semiprepared condition, thus throwing an extra amount of work on the intestinal digestion.

Turck has very ably demonstrated the intimate relationship in many cases of diseases of the mouth and nasopharynx with chronic inflammation of the stomach and intestines. He shows that often the microorganisms producing the fermentation and putrefaction in the stomach are identical with the ones found in cultures taken from the mouth and nasopharynx of the same patient.

Stark maintains that there is a frequent relationship between caries of the teeth and enlargement of the cervical lymphatic glands, and it is well known that otitis media sometimes results from this source.

From what has been said, it is evident that there is a close relationship between caries of the teeth and diseases of the stomach. If we are to have good health, we must have good food properly prepared, thoroughly masticated, well digested and absorbed. It should be a routine practice to examine carefully the mouth of every patient, and if the teeth are not in good order, the patient should be advised to see a dentist, and have them properly treated. The nose and nasopharynx should also be examined, and if diseased should receive appropriate treatment. It is only by careful attention to these and other details that we can hope to achieve the best results in the treatment of gastrointestinal diseases. A large number of these cases require the most skilful attention on the part of both physician and dentist.

The loss of teeth means imperfect articulation, absorption of the alveolar process, falling of the muscles, injury to the nerves, undue pressure on the remaining teeth, impaired beauty and symmetry of the face as well as imperfect mastication of the food.

Patients should be urged never to have a tooth extracted that can be repaired unless so advised by a competent dentist. More attention should be given to the teeth in childhood. Care should be taken to prevent decay around the temporary teeth, so that the germs of the permanent teeth may be kept in a healthy condition. It is the duty of every parent or other person entrusted with the care of children to teach them to brush their teeth after each meal. The child should be taken to the dentist every 6 months or year and have the teeth thoroughly inspected and all defects promptly corrected. Irregular teeth interfering with the articulation should receive appropriate treatment. Rough surfaces should be made smooth and cavities well filled, since food does not tend to collect so much on teeth with smooth surfaces in a healthy mouth. There is nothing that will pay better interest on the small amount invested or result in more satisfaction to the patient in after years than the possession of good teeth and good digestion.

The welfare of every individual cell in the human organism is dependent on digestion and nutrition. Poor teeth and improper digestion predispose the patient to many of the constitutional diseases. On the other hand, many constitutional diseases influence the teeth and the digestion, such as anemia, syphilis, etc.

Looking at the subject purely from an esthetic standpoint, what is more disgusting than a man or woman with half of the front teeth missing and the remaining ones all covered with tartar and food in all stages of decomposition, and whose breath reminds one of the odor of a cesspool?

When patients have plates in their mouths, they should

remove and cleanse them after each meal. If the plate is not frequently removed, the food accumulates beneath the plate and furnishes favorable conditions for fermentation and putrefaction, with quite as serious results as occur with carious teeth.

In acute fevers great care should be given to keeping the mouth and teeth well cleansed, because the salivary secretion is diminished in quantity and is not capable of even approximately neutralizing the acids which are formed. During pregnancy women should take extra care of the teeth, for it is a common saying with obstetricians that for every child the woman will lose a tooth. This can generally be prevented, with proper care.

Among the predisposing causes of caries are too rapid development of the teeth, deficiency of lime salts in the body, rachitis, tuberculosis, syphilis, defective structure, imperfections in the dentine and enamel, irregular teeth, favoring the retention of food between the teeth, and finally, certain diseases that produce an acid reaction of the mouth.

By what has been said I do not wish to convey the idea that I consider pathologic conditions of the mouth the only cause of digestive diseases, but that the neglected mouth with carious teeth is one of the important factors, and one that has received altogether too little attention by the general practitioner.

A LARGE SPLINTER DRIVEN THROUGH THE GREAT SCIATIC NOTCH.

BY

LOUIS SPITZ, M.D.,

of Philadelphia.

About August 12, I was called to see a young married woman who, about 7 months previous had fallen through a skylight, landing upon her buttocks on a rickety chair; one of the rungs broke and penetrated (as she explained) the rectum. The broken fragment of wood was removed by her husband and a physician sent for. The wound was dressed and redressed, ointments and powders of every description applied, but the so-called scratch persisted, together with a sanguinopurulent discharge. The patient stated that while the pain was not of an excruciating character, it was sufficient to prevent her assuming the regular sitting position, she was obliged to either stand, lie down or rest on a chair with legs crossed under her, tailor fashion. She complained of no other symptoms than those of the offensive discharge and the accompanying discomfort. Her bowels were regular, but at times the stools were bloodstained. Before examination I concluded that I had to deal with a fistula in ano, but an examination revealed a more complicated matter. With the patient in the kneechest posture, I passed a probe about 10 cm. through the external wound, and with the index finger of the left hand in the rectum I could not feel the distal end of the instrument. Realizing at once that this was either an anal fistula with the internal opening exceedingly high up, and therefore in imminent danger of entering the pelvic cavity, or a canal of considerable depth which was blind internally, I advised early operation, but consent to operate was not obtained until nearly 2 weeks later, when some alarming symptoms arose. At this time, August 14, the wound had bled quite freely and the patient complained of pain in the region of the pelvis. On palpating the lower abdomen no tenderness was found, but there was considerable soreness around the site of the fistula. A thorough examination of the heart, lungs, etc., revealed nothing abnormal; the blood and the urine were examined with negative results. On August 16, operation was performed, with the patient in the lithotomy position. The external wound was enlarged sufficiently to admit a finger, and as the tract was lined with necrotic tissue, I cut away all the visible dead tissue. Passing a probe through the opening, I discovered that the sinus led in the opposite direction from the rectum, and as the probe went in fully 12 cm., I was apprehensive as to what might yet be disclosed.

Confident of not entering the rectum, unless perhaps I was obliged to face an unfortunate anomalous condition, I scraped the canal as clean as possible with a sharp curet, flushing it out at the same time with normal salt solution. Again the probe was passed and this time something hard was felt at the end of the instrument, and a small, irregular resisting body could be outlined. After considerable effort a piece of wood about 6 cm. in length was extracted. This was the largest of about 10 fragments which had become lodged and partially encapsulated. The wound was thoroughly curetted and irrigated and packed with iodoform gauze. From the beginning the field of operation was entirely concealed from view and I had to depend

entirely on my fingers. The great danger lay in the close proximity of the pelvic cavity and for this reason I was most careful in introducing sharp instruments. No difficulty was experienced in dissecting through the superficial anal muscles, but the ischial tuberosity formed a barrier whereby the continuity of the canal was prevented. The bent probe overcame this obstacle and the instrument passed on through the fat in the ischio-rectal fossa and through the superficial and deep triangular ligaments with the intervening levator ani between whose fibers some of the smaller fragments were found; the larger piece perforated the sheath of the muscle, and lay just beneath the rectovesical fascia.

On the ninth day succeeding the operation the wound was entirely healed and the patient wholly free from pain or discomfort. She menstruated the third day after the operation, but manifested no untoward symptoms during the progress of this function and went on to an uninterrupted recovery. About 2 months later I saw her again and found that she was completely cured.

POTASSIUM IODID IN HEMIPLEGIA.

BY

M. J. PAYNE, M.D.,

of Staunton, Va.

To the Editor of American Medicine:—Having had occasion to push the administration of potassium iodid in a case of hemiplegia and associated aphasia, with the purpose of producing the full therapeutic effect, and being unable to bring about iodism, even when the dose far exceeded what is stated to be the maximum dose, I have decided to ask the readers of *American Medicine* what, in their experience, has been: (1) The maximum dose given; (2) has iodism invariably been observed; (3) what was the method, and the frequency of administration?

The patient in question took at 1 dose 13.61 gm. (210 gr.), this dose being given 3 times in 1 day. The c.p. potassium iodid was used, and iodism was not observed. The method of increase was 1-gr. increase at each dose, and given 3 times a day.

This case would tax the so-called therapeutic test for specific infection beyond a reasonable limit and I think would place a question of interest before the profession. In other words, would this case, as cited, be classed as an exception to the therapeutic test, or as proof of it. The extreme tolerance has an explanation, and I would be pleased to have it from any one offering the solution.

HERNIOPLASTY.

BY

HERMAN B. GESSNER, M.D.,

of New Orleans, La.

To the Editor of American Medicine:—I write to suggest the use of the word "hernioplasty" to replace the expression "radical cure operation for hernia." The reasons for the substitution are, I believe, obvious.

Ventilation of Glass Pavilions for Tuberculous Patients.—One of the notable features of the glass pavilions for tuberculous patients at the Philadelphia Hospital is the treatment of the ventilation problem. Warm air forced into the rooms a little above the heads of the patients finds an outlet, as it cools, at about a foot from the floor. There is a continuous circulation. If Philadelphia, or any American city, should be suddenly covered up by some catastrophe and then explored, say 100 or 200 years hence, as the archaeologists have uncovered the ruins of Pompeii, the most surprising thing to the people of the future would be the lack of ventilation in the American house. Farm journals devote much space nowadays to ingenious plans for ventilating chicken houses; the cows in a modern dairy are provided with an abundance of good fresh air; but the architect has neglected the human occupant of the house. The ordinary house of an American city is a barbarous survival in civilization. It may be a model of convenience; the plumbing may be perfect; the ornamentation is perhaps artistic and pleasing; but in the great essential of furnishing the tenant with fresh air it is an anomaly—almost a crime.—[*Public Ledger.*]

DIAGNOSIS AND TREATMENT OF THORACIC ANEURYSM.

BY

STEPHEN SMITH BURT, A.M. (Yale), M.D. (Columbia),
of New York City.Professor of Medicine, New York Post-Graduate Medical School and
Hospital.

The evidences of an aneurysm of the thoracic aorta differ somewhat with the position of the dilation. Indeed, small sacculated aneurysms may occur, especially at the beginning of the aorta, with nothing to suggest their presence until the final rupture and hemorrhage. But, ordinarily, these tumors are marked by physical signs or pressure symptoms or both combined in varying proportions. I propose to review these evidences and to cite a number of instances in illustration. Aneurysms are more liable to develop in men than in women because of the greater arterial strain to which men are commonly subjected, and because of their greater proneness to alcoholic and venereal incontinence and their resulting vascular degeneration. Almost as many aneurysms occur before 40 as afterward. The thoracic aorta is most frequently affected in the ascending portion of the arch, which is in the direct line of the greatest intravascular pressure. Next in frequency is the transverse, then the ascending and transverse arch conjointly. Next in order are the sinuses of Valsalva, then the descending portion of the arch, then the section of the thoracic aorta below the arch, then the whole arch, and, finally, the transverse and descending subdivision. Broadly speaking, whenever upon the surface of the thorax there is a pulsating tumor which is not the heart, but which is beating with coequal force and rhythm, whether or not there is a murmur, in all probability it is a thoracic aneurysm. However, the difficulties of diagnosis are not when the conditions are so clearly obvious as implied by this general statement. Aneurysmal tumors of the sinuses of Valsalva may exist without any manifestation. A growth of this kind in the ascending portion of the arch commonly extends to the right of the sternum above the level of the fourth rib, or, less often, to the surface directly forward. Now and then it appears at the left of the sternum. Aneurysms of the transverse arch press backward toward the spine or forward under the sternum, and may be appreciable in the suprasternal region. When the sac involves the ascending and transverse portion, it passes to the right and upward. In aneurysm of the descending portion of the arch, it extends to the left and backward. A tumor situated at the junction of the transverse and descending portions grows from behind the sternum to the left and upward. Aneurysms below the arch are generally located just above the diaphragm. By physical examination we find on inspection, if the tumor projects through the chest wall, a heaving, expansile pulsation. If it arises from the first portion of the arch the tumor usually points in the vicinity of the second intercostal space to the right of the sternum. If from the second, it comes through the upper part of that bone. When from the third division, it appears to the left of the sternum above the third rib, or to the left of the spine about on the same level behind. Aneurysms of the descending thoracic aorta pulsate to the left of the spine a little lower posteriorly. When the tumors do not stand out on the surface, there may be simply varying degrees down to entire absence of pulsation in these several localities. Sometimes the movement is so slight that it can be seen only under a strong light and by looking sidewise. A large aneurysm when filled with fibrinous laminae may exist without the slightest visible pulsation.

When the heart is laid bare by retraction of the lung, or by some spinal deformity, cardiac impulse at either

side of the sternum must not be mistaken for that of an aortic dilation. An enormously enlarged or scolloped bovine heart may crowd the aorta toward the right until the displaced vessel simulates an aneurysm. As increased size of the heart, in the absence of valvular disease, is not a concomitant of these affections, any dislocation of the apex ordinarily is caused by pressure rather than by enlargement. When venous congestion and swelling of the right arm are present, the tumor is probably in the ascending portion of the arch and is pressing upon the subclavian vein; there is engorgement of the head and upper extremities when the pressure includes the vena cava superior. Should the tumor involve the inferior vena cava there would be swelling of the lower extremities. Pressure upon the venous system is said to occur more commonly when the growth is nonaneurysmal. It was well marked, however, in a case of mine, in which the aneurysm, though springing from the third division of the arch, extended widely in all directions. If, on looking into the larynx, there is paralysis of the right vocal cord, it may be due to pressure in the ascending arch upon the recurrent laryngeal nerve. If the right pupil is abnormally dilated or contracted, there may be varying degrees of pressure in the ascending arch upon the sympathetic; simple irritation results in dilation, destruction of the nerve in contraction. Deep-seated pressure, however, is much more apt to occur in the transverse portion of the arch than in the ascending. Another explanation of the alteration of the iris is based upon changes which take place in the tension of the bloodvessels of the eye, as a result of the disturbance of the general circulation. If the left vocal cord is paralyzed, the sac is in the transverse portion of the arch, and is pressing on the left recurrent laryngeal nerve. With the tumor similarly situated, also there may be either left pupillary dilation or contraction. The trachea may be pushed backward by an aneurysm in this region or otherwise displaced. Exophthalmos on one or both sides may be due to aneurysm. Likewise a collar-like swelling around the base of the neck. Such a condition recently came under my observation. Clubbing of the finger-ends is rare in this disease. It has been seen upon one side alone. In large aneurysms of the transverse or the descending portion of the arch, there may be displacement of the dorsal vertebrae instead of pulsation in this neighborhood. In a case to be recounted, there was kyphosis in the upper dorsal region, involving the second, third, and fourth vertebrae, with no pulsation. In my opinion, aneurysms that are too small to be detected by the ordinary methods are too small to be seen in the hazy shadows thrown upon a screen by the röntgen rays. But the outlines of a large dilation of the aorta as depicted by these rays are valuable evidence and corroboratory. By palpation a projecting aneurysmal tumor is found to have a peculiar heaving, expansile pulsation that differs in character from the simple uplifting movement of a growth of another nature, wherein the pulsation is not inherent but transmitted. When the aneurysm has not perforated the chest wall, there are all degrees of pulsation down to a mere throb, which last is appreciated best with one hand on the spine and the other over the sternum. A diastolic shock is frequently felt over an aneurysm as well as a systolic impulse, but nevertheless, when the sac is filled with fibrin these may not be palpable. If there happens to be a systolic thrill, it is usually over a fusiform dilation, or else it is the result of an aortic valvular complication.

If a large sac involves the left carotid and left subclavian, the left carotid and radial pulses may be retarded, thus rendering the two sides unequal. An extreme dilation of the aorta which includes the innominate artery, or which comprehends the greater part of the arch, may absorb, so to speak, the arterial wave and leave nothing but a continuous stream for the distal arteries. Here there will be no beating pulse but still a circulation. Sir William Gairdner alludes to this loss of

elasticity in the larger dilations, and its consequences. Such a phenomenon has been observed also by William Osler in the abdominal aorta and the effluent arteries of the lower extremities. In this instance the continuous arterial flow was probably caused by a large over-distended sac below the left subclavian artery in the descending thoracic aorta, as the tumor was pulsating behind to the left of the spine in that vicinity. When the sac is filled with solid coagulum through which a good-sized channel is left intact, such as occurred in my experience, ventricular systole will be transmitted without interruption to the distal arteries, and the beating of the two sides will remain simultaneous. In aneurysms, especially of the transverse portion of the arch, a heaving impulse may be felt in the suprasternal notch, but examiners must be wary of this occurrence for it is not infrequently a normal manifestation. When an aneurysm is deep-seated and not rendered motionless by an organized internal clot its beating may be communicated

The aneurysm is to the right of the photograph, the sac torn in the removal, the clot exposed and a glass tube inserted in the channel. It was much larger in position than it appears in the photograph. Above and to the left are the three eroded vertebrae, with a glass tube projecting from the erosion into the spinal canal. Photographed by John W. E. G. Miller, M.D., instructor in medicine, New York Post-Graduate Medical School.

to the trachea. This is known as tracheal tugging, or Oliver's symptom, and since it is unusual with other growths of the mediastinum its diagnostic value is considerable. The test is applied in the following manner: Place the patient in an erect position and direct him to close his mouth and elevate his chin to almost the full extent; then grasp the cricoid cartilage between the finger and thumb, and use steady and gentle upward pressure on it, when, if dilation or aneurysm exists, the pulsation of the aorta will be distinctly felt transmitted through the trachea to the hand. When the aneurysmal sac impinges upon the wall of the chest, there will be abnormal dullness or absolute flatness on percussion over the area implicated. Should there be an external projection of the tumor, anything but the gentlest stroke would be dangerous, in fact percussion under these conditions is generally unnecessary, and forcible strokes over whatever degree of dilation are always inadmissible. Aneurysms of the ascending arch produce flatness to the right of the sternum above the fourth rib, and in

a somewhat higher position behind; those of the transverse arch give flatness over the manubrium and to the left in front, and at least marked dullness at about the same level posteriorly. The flatness of an aneurysm of the descending arch may extend from the sternum to the left above the third rib, and behind, from the level of the third or fourth dorsal vertebra to the left and upward. Very large aneurysms of the arch of the aorta irrespective of their exact points of departure may develop widespread flatness or dullness at the upper part of the chest behind as well as anteriorly. Upon auscultation there may be a systolic murmur over an aneurysm, though it is not essential to a diagnosis. If there is also a diastolic murmur it is probably due to aortic valvular insufficiency. There is commonly accentuation of the second sound over the tumor with a diastolic shock to the stethoscope. When the sac is well filled with fibrinous deposit, there may be neither shock, murmur, nor accentuation. Pulsations may be detected now and then by means of the stethoscope that are otherwise unappreciable. Sometimes a rhythmic murmur is audible through the mouth of the patient, especially when it is closed over the objective end of an adjusted stethoscope. The breathing in the vicinity of the tumor may be entirely absent or else diminished; but usually there are evidences of pressure short of occlusion of the trachea or the bronchi in the nature of widely diffused sonorous respiration. The point of greatest intensity of these breathing sounds can oftentimes be traced to the left bronchus or lower end of the trachea. Pressure and finally closing of the lower end of the trachea while in progress were recently under my observation; likewise in another instance, closure of the left bronchus through which the aneurysm eventually ruptured with fatal consequences.

Among the symptoms, sudden violent pain, which may extend down the left arm, is prominent. The distress due to erosion may be a constant dull aching, or it may be intermittent, of a severe tearing character. Dyspnea is usually present. When there is partial obstruction of the trachea, cough and a peculiar wheezing are heard. When the cough is metallic in character and paroxysmal, with loss of voice, there is generally pressure upon the left recurrent laryngeal nerve. Loss of blood in varying amounts is frequently associated with aneurysm. There may be simply blood-tinged sputa or an extensive hemorrhage. Moderate bleeding is not necessarily serious, but a profuse outpouring from the sac either internally or externally is likely to cause sudden death. The esophagus is more apt to be pushed aside than invaded by an aneurysm, and hence there is seldom difficult deglutition, whereas the opposite holds with growths that are malignant.

Transmitted pulsation by the heart to a pleural effusion, which is usually widely diffused, should not be confounded with the impulse of an aneurysm which is generally circumscribed. Physical evidences of free fluid in the pleural cavity are quite distinct from those of fluid in a sac that can be traced to the aorta by its various signs and pressure symptoms. Differential diagnosis between aneurysmal and other mediastinal tumors is sometimes a problem that requires for its solution the most serious consideration. 1. Aneurysms are more likely to be encountered than malignant growths in this neighborhood. 2. A patient with aneurysm is generally otherwise in excellent physical condition, while there is commonly decided cachexia when tumors are malignant. Hence, if the tumor has existed for a year or more, this fact strongly points to aneurysm, should the nutrition and complexion of the sufferer meanwhile remain undisturbed. Mediastinal abscess is likely to be associated with hectic fever symptoms, and moreover, a collection of pus always should be revealed in the blood by a leukocytosis. Pressure effects are quite as likely to occur from solid tumors as from aneurysms. Indeed, as before remarked, these effects are more often found with

the former in the venous and digestive systems. These tumors may also develop murmurs, but ordinarily they do not, like aneurysms, cause diastolic shock, tugging at the trachea, or inequality in the pulses of the arterial circulation. And when they project through the surface of the chest and pulsate by conduction, unlike aneurysms so situated, the motion is neither forcible, heaving nor expansile. Malignant tumors of the mediastinum are usually associated with glandular enlargement of the neck and upper extremities which is not the case with aneurysms. The peculiar paroxysmal pain radiating from a deep-seated aneurysm, especially down the left arm, is not common to other tumors of the mediastinum. Malignant growths are more likely to cause dislocation of the heart than are aneurysms. Although a recent case of aneurysm of the descending arch of the aorta, under my care, was associated with pleurisy, this complication is more characteristic of tumors that are nonaneurysmal. When a large sac is filled by laminated fibrin it becomes practically a solid tumor, and the difficulties encountered under these circumstances will be shown in two of the following examples wherein after deliberation the true condition was diagnosed.

The treatment of aneurysm chiefly consists in absolute rest, mental as well as physical, restriction in the amount of food, and especially of fluids, together with potassium iodid for medication. All these expedients are constituted to favor the deposition of fibrin in the sac which is thereby strengthened, and recovery practically accomplished. Sacculated aneurysms with relatively small openings are likely to receive the most benefit from treatment. The introduction of foreign bodies into the sac or the use of electrolysis to favor firm coagulation is not on the whole satisfactory. Nor are any of the numerous drugs not excepting ergot, aside from potassium iodid, that have been from time to time recommended, of value otherwise than as palliatives. Morphine, chloroform, applications of ice and of belladonna, and venesection, are most useful temporary expedients. Potassium iodid, irrespective of specific disease, certainly lessens pain and discomfort, and it may possibly cause the sac to shrink and the blood to clot with greater firmness. In my opinion, however, its supposed favorable influence on the deposition of fibrin is problematic. Not only small, but also large tumors continually are found, as far as possible cured by being lined or else obliterated by solid fibrin when neither potassium iodid nor other drugs had been administered. On the other hand, a prolonged course of potassium iodid not infrequently has been known to end fatally in rupture of the sac without any fibrinous deposition. In one of the cases cited, the tumor had been thickly lined, and in another filled, by fibrin before the beginning of treatment, though they were both large-sized aneurysms. In one case there was room for the sac in the direction of its growth, which was from the ascending branch of the aorta into the right side of the chest, and the patient not being vitally injured thereby, recovered; in the other, the aneurysm invaded the spine by erosion, and eventually closed the trachea by pressing forward, and caused death by suffocation. In a third case, the patient, though put on light diet, confined to his bed, and treated with potassium iodid, suddenly died by rupture of the unhealed sac into the left bronchus, the rupture causing a profuse external hemorrhage.

CASE I.—T. L., aged 45, married, occupation carpenter, was admitted to my service December 23, 1902.

Family history is negative.

Previous History.—When 19 he had a sore on the prepuce, but there was no inguinal adenitis and no skin eruption. Other facts are unimportant.

Present History.—Three months ago he fell from a ladder, striking the back of the right chest, which resulted in a severe local pain that disappeared next day, and he resumed work. He was able to continue for awhile with but slight discomfort, until an acute pain appeared over the sternum and to the right

of the manubrium. This pain radiated backward and upward posteriorly. Shortness of breath on exertion slowly developed. In using the plane or the saw the pain became so severe that finally he was obliged to abandon his occupation. Lately he has had slight pain when lying still and severe pain on exertion.

Physical Examination.—He has a healthy color, and is well nourished. His pulse, temperature and respiration are normal. There are no objective pressure signs. Heart is normal, apex not displaced. Inspection is negative. Palpation discovers absence of vocal fremitus to the right of the sternum above the fourth rib. No pulsation. On percussion there is dullness over the right chest down to the fourth rib in front, and flatness in the region of the second intercostal space extending 2½ inches to the right of the sternum. Abnormal dullness on this side behind over the upper third of the scapula. On auscultation, a faint systolic murmur in the third interspace close to the sternum is discovered. No accentuation of the aortic second sound. No tracheal tugging. Lungs are normal elsewhere. My diagnosis was sacculated aneurysm of the ascending branch of the aorta with sac obliterated. After 2 weeks in bed, upon restricted diet and .6 cc. (10 m.) of a saturated solution of potassium iodid 3 times a day, the pain, which had continued over the area of flatness, disappeared. Subsequently the roentgen ray was employed, and an opaque mass was seen extending about 2½ inches to the right of the sternum, from the second to the fourth rib, and in connection with the aorta. Thus my diagnosis was corroborated. Examination of the urine was negative. There were no tubercle bacilli in the expectoration. The patient, practically cured, was up and about the ward, and was discharged on February 18.

CASE II.—T. D., aged 34, single, occupation clerk, came under my care December 1, 1899.

Previous History.—He had rheumatism when 16, and pain in the chest a year ago.

Present History.—About 10 weeks ago he was taken with pain in his chest under his left shoulder blade; the pain was most severe upon inspiration. He complains also of pain which extends into the left shoulder and down the left arm. No history of hemoptysis. Examination of the urine was negative. There were no tubercle bacilli in the sputum. Patient was well nourished.

Physical Examination.—The apex beat of the heart, which was forcible, was below and to the left of the normal position. Respiratory action of the left side was restricted. There was pulsation in the same rhythm, though not of the same strength as that of the heart, on the left anterior part of the chest above the third rib. Vocal fremitus was absent over the entire left side of the chest. In the pulsating surface there was no thrill. The left side was not increased in measurement. On percussion, there was flatness over the lower two-thirds of the left chest; dullness on the same side at the upper part behind; a triangular area of exaggerated resonance, with base in the upper left axillary region, and apex extending forward, located between the flatness below and the pulsating area above, previously mentioned; flatness from near the right edge of the sternum across to the left above the level of the third rib. Auscultation revealed an absence of any kind of breathing over the entire left side of the thorax. There was a loud, rough, systolic murmur, with point of greatest intensity at the second right cartilage, extending across the chest to the left in the track of the pulsation. The second aortic sound was accentuated, but not widely transmitted. My diagnosis was aneurysm of the descending arch of the aorta, with occlusion of the left bronchus, complicated by aortic valvular obstruction and left pleuritic effusion. In this case, pain was the subjective pressure symptom, and closure of the left bronchus the objective. The pain was in the left chest and down the arm of that side. The area of flatness, wherein there were pulsation and systolic murmurs, was distinct from the region of flatness below; an interval of hyper-resonance intervening.

Treatment consisted of rest in bed, restricted diet, and .65 gm. (10 gr.), gradually increased to 1.3 gm. (20 gr.), of potassium iodid 3 times a day. The patient died suddenly, December 20, of a profuse arterial hemorrhage, with no previous history of bleeding, from rupture of the sac into the left bronchus and trachea. No necropsy was performed. Granting that the aneurysm projected to the left and forward from the descending arch of the aorta, it must have originated below the left subclavian artery, because there was nothing to indicate pressure above this location. The entire absence of all breathing sounds in the left lung, even above the pleuritic effusion, was evidence of the closure of the left bronchus.

CASE III.—E. T., aged 37, colored, married, occupation porter, was admitted to the hospital December 6, 1899.

Previous History.—He never had syphilis; there is no history of alcoholism.

Present History.—One year ago he was taken with a sharp pain in the left side, of a week's duration. Since then he has had repeated attacks of pain in the chest, back, and shoulders. He was obliged to give up work. At night he has a feeling of oppression in the chest, and for the past week he has had a choking sensation. Examination of the urine is negative, excepting for a small trace of albumin. Pulse, respiration, and temperature were normal on admission. The patient had a vigorous frame and was well nourished. His extremities were neither edematous nor paralyzed. Although there was no

aphonia there was hoarseness with a cough that was harsh, but not metallic. He made no complaint of dysphagia.

Physical Examination.—The vocal cords were seen to be normal through the laryngoscope; the apical impulse of the heart was not displaced; no visible pulsation in the chest elsewhere. The superficial veins of the neck and both arms were distended. Around the base of the neck there was a spongy elastic swelling, and in the upper dorsal region an angular curvature of the spine with convexity backward. The spinous process of the third dorsal vertebra was especially prominent. Neither inequality of the pupils nor unilateral sweating was present. Pressure upon the second, third, and fourth dorsal vertebrae was decidedly painful. The apex beat of the heart was normal in force and position. The beating of the radial arteries was equal in strength and rhythm; there was no shock, pulsation, or tracheal tugging palpable. On percussion, flatness with striking resistance was found extending from 1 inch to the right of the sternum, across and for 3 inches to the left of that bone, and from the level of the insertion of the third ribs in this region upward; also abnormal dullness behind, from above down to a horizontal line intersecting the third dorsal spine on both sides of the thorax. Marked vesiculotympanic resonance was noted at the back over the lungs, from thence downward. Auscultation showed sonorous breathing over the entire chest, with the point of greatest intensity at the lower end of the trachea and the left bronchus; that vesicular respiration was masked by the sonorous breathing; no cardiac murmurs; no thrill or murmur over the area of flatness. The heart sounds were not intensified, and there was neither systolic nor diastolic shock over the tumor or the trachea. Upon a subsequent examination, a slight fleeting pulsation was detected chiefly by means of the stethoscope over the region of flatness on the left side anteriorly.

My diagnosis, after a thorough study of the case was aneurysm of the descending portion of the arch of the aorta, pressing upon the vertebrae behind, and in front, on the lower end of the trachea as well as the left bronchus. The location of the seat of the tumor was based on the positive evidences of pressure upon the vertebrae, the trachea, and the left bronchus, and on the negative evidences, namely, the absence of signs of pressure upon the left recurrent laryngeal nerve, or the sympathetic, or the left subclavian artery. The nature of the tumor primarily was decided by the vigorous frame and well-nourished condition of the patient, which, despite the duration of the malady, had been maintained, together with the absence of any trace of malignant growths elsewhere, or of glandular enlargement. These, in connection with the history, age, sex, occupation of the patient, and the results of medication, led me irresistibly to my conclusions.

Treatment consisted chiefly of rest in bed, a light diet, and 1 gm. (15 gr.) of potassium iodid 3 times a day, with now and then as required, morphin hypodermically. All tenderness of the vertebrae entirely disappeared under potassium iodid. The daily notes showed that the temperature remained about normal; the pulse varied between 80 and 100, the respirations between 20 and 30 per minute. He never complained of difficulty in swallowing. The bowels were constipated. Hemorrhage did not take place. There was no paraplegia. He had dyspnea, with a hoarse cough, which was not metallic in quality, and a slight mucous expectoration. Although less uncomfortable when in the dorsal decubitus, there was always great restlessness. He complained of a feeling in the chest of fullness and of oppression. There were frequent paroxysms of pain and dyspnea, but above all, toward the end, distressing dyspnea, which ended in death by asphyxia, December 29.

From the records of the necropsy, which took place January 3, 1900, the following relevant features are abstracted: "E. T., colored, general condition, well nourished. Marked kyphosis in the upper dorsal region. There was a large sacculated aneurysm in the descending portion of the arch of the aorta, beginning about $\frac{3}{4}$ inch beyond the origin of the left subclavian artery, and situated behind the trachea, and filling the upper quarter of the left thoracic cavity, together with the posterior mediastinum, and extending about 3 inches into the upper part of the right thoracic cavity. The tumor pressed forward against the lower part of the trachea and the left bronchus, but was not adherent. It likewise compressed the vena cava superior and the vena innominatae. The walls of the aneurysm were adherent on the posterior aspect to the spinal column, and on the right side somewhat anteriorly to the esophagus. The latter, with canal still patent, seemed to have been carried forward and outward on the right side of the tumor, to which it was closely attached for about 4 inches; the aneurysm was filled with a dense laminated fibrous clot, through which was a free channel about equal to the aorta in dimensions, and it was of an irregular ovoid shape, and from 6 inches to 8 inches in its long diameter. The bodies of the second, third, and fourth vertebrae were extensively eroded, and the erosion of the third vertebra opened into the canal of the spinal column. The interarticular discs were practically unaffected. The borders of the second, third, and fourth ribs near the spine were roughened and slightly eroded."

Physician Wanted.—A correspondent writes, under date of February 1, from Fort Jennings, Ohio, that a physician is needed in that place. Young doctors seeking for places of location might do well to investigate.

RETROPERITONEAL INFECTION A RESULT OF APPENDICITIS.

BY

I. S. STONE, M.D.,

of Washington, D. C.

Surgeon to Columbia Hospital, etc.

The controversy between the advocates of the intra-peritoneal and extraperitoneal origin of perityphlitis, or suppuration near the cecum, which raged for a time, diminished in violence only to be renewed when Sir Frederick Treves operated upon King Edward. The disputants were alike mistaken, for each declared his position the only correct one. The "intras" said all the trouble came from appendiceal rupture into the peritoneal cavity, while the "extras" with equal vigor asserted that appendicitis was a nightmare, and that it was all "para" or "peri" typhlitis.

It is beyond question, however, that the older pathologists and surgeons knew what was meant by retroperitoneal infection, and we find that in 1834 Dr. James Copland, in his Dictionary of Medicine, clearly discriminated between inflammation of the cecum, the vermiform appendix, and the pericecal tissue¹ (quoted by Fitz).

A little before this date, Goldbeck² wrote a thesis upon perityphlitis,* and Dance and Husson³ inspired by Dupuytren,⁴ wrote an account of the suppurative diseases about the cecum.†

In 1836, Addison,⁵ of London, published a work on typhlitis, and also lectured upon this subject prior to that date. Melier⁶ and Burne,⁶ in 1837, Hancock, 1848, and Willard Parker,⁷ 1867, (see reference, W. Parker) were pioneers in the study of the subject at the operating table, and in the dead house.

Samuel Wilks,⁸ of London, in 1859, wrote upon the various inflammations around the cecum, and demonstrated their origin, in both the appendix and cecum. It is only fair to observe that the earlier writers failed to understand the real nature of "typhlitis," and it is perhaps true that Burne was among the first, if not the first, to discover a relation between appendiceal disease (ruptured?) and the resulting abscess in the right side, "typhlitis" or "perityphlitis."

A little later, Dr. James H. Pooley,⁹ of New York, reported 46 cases of retroperitoneal abscess; all the patients recovered after operation, save 5. Of these 5 fatal cases, "3 patients had peritonitis, 1 had abscess of the lung, and 1 died of asthenia."

Since the work of these men we have a better idea of the role of infection, as we have also a better knowledge of surgical anatomy and of how the morbid process extends from the bowel by way of the appendix, not to the peritoneum alone, but under certain circumstances to the connective tissue, lymphatics, and vessels outside of that membrane.

Frequency.—In 100 observations Wier¹⁰ found 85 cases of peritonitis, 5 of extraperitoneal suppuration, and 9 of both (mixed) intraperitoneal and extraperitoneal suppurations; 14.9% of extraperitoneal infection, and 4.6% without associated peritonitis.

Maurin, quoted by Fowler,¹¹ found in 94 fatal cases 5 extraperitoneal, and 9 mixed, or intraperitoneal and extraperitoneal infections. There were 4.6% of purely extraperitoneal infections and resulting suppurations, without peritonitis.

Ferguson¹² says that in 77 of 200 cases in 35% "the appendix was so placed and covered by peritoneum that its perforation would have opened into subperitoneal tissue and a diffuse cellulitis would have resulted."

* It is claimed by Willard Parker that a German, named Purchett, was the first to use the word perityphlitis. Virchow was the first to suggest the name paratyphlitis.

† It is said by Vladoff that Mestliver in 1759 was the first to describe the suppurative diseases of the appendix and cecum, and that Albers, of Bonn, first used the name typhlitis.

Hawkins,¹³ who has written a most admirable work upon the diseases of the appendix, assumes that the appendix is always intraperitoneal,* yet says: "Iliac abscess may form as a result of perforation of an appendix already adherent on the posterior peritoneal surface." (Hawkins, op. cit., p. 92.)

R. H. Fitz¹⁴ found 11 posterior infections in 257 cases of appendicitis.

J. B. Deaver¹⁵ found 174 cases of posterior infection in 413 patients treated in 1 year (1901). Of these, 41 cases were retrocecal.

Langhelt, of Berlin, in 112 autopsies (*vide* Loison¹⁶) found 4 cases of thrombophlebitis, 2 of hepatic abscess, 2 of hepatitis, and 2 of perihepatitis.

Einhorn (*vide* Loison), of Munich, found in 100 autopsies 6 cases of infectious embolism of the vena porta, and liver abscess.

G. R. Fowler (op. cit.) appears to confirm the opinion of Fergusen and others that in a large proportion of cases the appendix is not entirely within the peritoneal cavity, or, in other words, is not entirely enveloped by that membrane, and "the uncovered portion is in direct contact with the subperitoneal connective tissue."

Beside the authorities above named, a large number of writers have not only recorded their observations, but have, in addition, reported cases in support of their views. From among the very large number of cases of postperitoneal infection, we have selected for consideration those reports in which the patient had infection immediately behind the peritoneum rather than those

finally, lumbar abscess, incision. The other patient had decided septicemia with acute symptoms, chills, and sweats. First operation, appendicectomy, July 26; second (postperitoneal abscess) August 28. Both patients recovered.

Among other operators who have recorded their cases are: M. L. Harris,¹⁸ Graham,¹⁹ Brault,²⁰ Stepp,²¹ Mynter,²² Gittings,²³ Nash,²⁴ VanderVeer,²⁵ H. C. Deaver,²⁶ LaPlace.²⁷

How Infection Reaches the Retroperitoneal Space.—Having reached the conclusion that a large number of fatal cases of appendicial disease is directly due to retroperitoneal infection, we have to consider how and by which route infection spreads to the deepseated tissues and organs in question.

1. It may proceed directly through the peritoneum to the cellular tissue behind, from an intraperitoneal abscess (necrosis).

2. It may reach the cellular tissue from a rupture (perforation) in a congenitally displaced appendix,* (retrocecal,) or rupture into the mesoappendix, and this may be accomplished without intraperitoneal infection.

3. Infection by way of blood or lymph channels.

We know that communication between the appendicular and the portal veins by way of the ileocolic and splenic veins, is direct, and accounts for many of those dangerous infections of the liver and other organs† (pylephlebitis).

The Position of the Appendix and its Relation to Retroperitoneal Infection.

—From our own observations we believe that in at least 2%, and possibly 5%, of all bodies, the appendix lies in some part of its length outside the peritoneum, or behind the cecum, or in contact with its muscular wall. Maucilaire²⁷ gives us an excellent idea of the retroadherent appendix‡ and we reproduce one of his illustrations.

The direction of the diseased appendix has much to do with the results of its infection and possible perforation. Those cases in which the organ is to the left of the cecum, or east, to southeast, are most dangerous on account of the proximity of the mesenteric vessels and lymphatics. Thrombosis will result from an infection of these vessels and a train of complications follow, whose end may not easily be foreseen.

In a review of 572 cases by Monks and Blake,²⁸ they report the appendix down and inward in 179 cases; down, 29; in, 62; up, 52; up and in, 39; up and out, 29; out, 9; down and out, 5; unclassified, 14; behind the cecum, 104, or 18.2%.

Fergusen in 200 cases found the appendix toward the posterior surface of the cecum in 75; toward the right side in 19; within, 18; downward, 11; 77 times under the peritoneum. Vladoff and Clodo say the appendix is most frequently found pointing downward or toward the bladder and rectum (41.5%); upward along the side of

* If in 26% of all bodies the appendix lies more or less behind the peritoneum, this fact may be taken into account.

† The coincidence of appendicial and tubal or ovarian disease may be explained in a similar manner.

‡ Other writers also have described this situation of the appendix. (See Deaver.)

Fig. 1.—Shows the branches of the ileocolic vein which may transmit infection from the vicinity of the appendix to the mesenteric and splenic veins. Infection of and occlusion of the vessels in this region caused the fatal result in our fifth and sixth cases. (Adapted from Gray's Anatomy.)

telling of remote infections, such as pulmonary, splenic, or hepatic suppurations. In many instances our efforts should be directed behind as well as inside the peritoneum, if not while the abdomen is open, then as a *dernier ressort*, immediately afterward, or as soon as required for urgent symptoms which may not have yielded to the customary intraperitoneal technic.

J. F. Baldwin¹⁷ has collected 43 cases of deep infections (including subphrenic abscesses). His own 2 detailed cases were due to retroperitoneal suppuration. One patient had persistent elevation of temperature and pulse after an appendicectomy, which continued for 44 days (June 6 to July 20) "yet without chills or sweats;"

* Troves, Kelyneck and Hawkins declare the appendix to be "always intraperitoneal."

Fig. 2.—Shows a posterior view of the cecum and a small portion of the ileum. The appendix is shown in its retrocecal position. The perforation marked (B) caused the death of the patient. (From Maucilaire, *Bul. de la Soc. Anat.*, Paris, 1897, p. 110-112.)

the colon in 13 (13%); in 9.5% of cases partly or entirely placed outside the peritoneum.

As before stated our observations lead us to the conclusion that* an adherent appendix pointing anywhere east or south, is located over most important territory, and deepseated infections resulting in septic complications occur most frequently in this manner. The inflamed appendix, when pointing toward the right side, or when adherent to the abdominal wall or on the right of the ascending colon, is favorably situated. Its rupture and resulting abscess, when in this position, may be readily handled by way of an anterior or posterior abdominal incision.

Those appendiceal abscesses reaching far up outside the colon may be drained by posterior incision above the iliac junction, in addition to the anterior incision. Such posterior location of the appendix in our experience has not produced systemic infection, nor have these suppurations been difficult to reach and drain. (Note subphrenic abscess.) On the other hand the infections resulting from perforation of the adherent appendix when east to south, have occasionally produced suppuration leading to pylephlebitis and remote abscesses. If the connective tissue below the pelvic brim is infected, gravity will favor extension of the infection toward the deep pelvis, bladder, or femoral ring along the iliac or psoas muscle. Per contra, infection above this point may ascend toward the diaphragm and penetrate to the pleura or mediastinum. In this outline of our subject we can only mention possibilities, and frankly admit how difficult it is to discover at the time of operation in what way the infection has entered the retroperitoneal tissues, whether by way of direct transperitoneal or extraperitoneal route. Our aim in this paper has been to establish the fact that retroperitoneal infection is a serious and not infrequent complication of appendicitis, and that the position of the appendix in relation to the peritoneum may furnish an explanation of these results.

Symptoms.—The symptoms of retroperitoneal infection are mainly those of septicemia in addition to those of appendicitis. But there are some important and characteristic points of difference which require a detailed description. As seen in the statistics, quoted from several authors, retroperitoneal infection can occur without associated appendicitis. It would be quite as well, or perhaps better, to say that perforation and retroperitoneal infection and suppuration can and do occur without peritonitis. In such cases we have the symptoms due to infection of the lymphatics, vessels, or connective tissue, with immediate systemic manifestations.

In this form of sepsis we have frequently observed rigors or chills and sweats, although occasionally these symptoms are absent. When present we may anticipate pylephlebitis with streptococcic infection of the organs in the upper abdomen or chest.

Persistent high temperature and quick pulse after appendicectomy should always lead us to suspect "posterior" complications. In the "delayed cases," in which 1 or 2 weeks have elapsed before operation, such symptoms are very significant. In these patients with appendicitis as a preliminary stage, we occasionally find improvement for 1, 2, or possibly 3 days after appendicectomy. Then a rise of temperature and pulse, with increased pain and malaise, will indicate a deeper infection. If such a rise occurs and is maintained, an explanation must be found. Such complications do not pass with some slight cleansing of the wound, or by attention to the patient's bowels. Under such circumstances, if one is absolutely sure of a clean peritoneum, he must not fail to remember the possibility of retroperitoneal infection. We have occasionally seen such symptoms after an ideal operation, and have seen them disappear, even after manifestations of general sepsis with

icterus. But such favorable termination is not the rule, but an exception. If these symptoms of sepsis have appeared prior to appendicectomy, it is absolutely necessary that we should, at the time of operation, attempt to check what may become systemic infection.

ILLUSTRATIVE CASES.

CASE I.—Retroperitoneal infection found at time of operation. Recovery.

Miss L., aged 16. Previously healthy without history of previous attack. Present attack began 4 days before consultation. The patient was seen with Dr. Appleby, her family physician, January 12, 1898. Her symptoms indicated a mild attack of appendicitis without peritonitis. A mass could be felt behind or under the cecum, and we expected to find an abscess. There were no signs of general sepsis, nor was the pulse very quick. Highest temperature 102°. At the operation the appendix was found adherent to the peritoneum below the mesentery of the colon pointing "south." It was necrotic and surrounded by pus with fecal odor. Indications of retroperitoneal infection necessitated incision of the peritoneum, and we found a second abscess containing about an ounce of pus. Careful drainage was instituted by the transperitoneal route. Our drainage-tube was expelled from behind the peritoneum on the tenth day. Some days after this, a discharge of creamy pus escaped suddenly from the wound, and evidently came from the space we had drained behind the peritoneum. After this time there were no further accidents, and a complete recovery ensued.

CASE II.—Appendicitis developing during convalescence after abortion. Prolonged fever and finally iliac abscess. Operation. Recovery.

Mrs. K., aged 27, had a miscarriage of a 6 weeks' fetus in February, 1898. As she was a member of a prominent family, several physicians were in attendance, and she was most carefully watched and every precaution taken to insure absolute asepsis. I saw the patient 3 weeks after her illness began, and consequently all evidence of miscarriage had disappeared. The patient had fever and sepsis, which had refused to yield to treatment. Her history gave but little evidence of the real nature of her illness. The fever was thought due to the miscarriage, and as no cultures were made, the interior of the uterus was "suspected" and appropriate treatment instituted, with the hope of checking the disease.

Careful examination showed no abnormality in or about the uterus or broad ligaments, but an induration extending from the cecal point to and filling the right iliac fossa was easily located. The location of this pus was quite characteristic. It was not precisely in the line of the psoas muscle, being rather more to the right. At the time it was thought that its origin might be tuberculous. It was evidently not in tube, ovary, or broad ligament, consequently an incision was made above the crest of the ilium, downward and forward outside the peritoneum, and the abscess was reached without entering the peritoneal cavity. The odor of the pus was characteristic of fecal contamination, and we easily located its origin at the cecum. The patient made a rapid and satisfactory recovery.

CASE III.—The patient had symptoms of rheumatism. Then a retroperitoneal abscess was discovered, which explained the symptoms. Recovery.

H. F., aged 16, with a history of one attack of appendicitis, had a second attack July, 1899. The usual signs of appendicitis without rupture or peritonitis, with hard mass under cecum, indicated an abscess already formed.

The patient had what is usually called a "mild attack;" there appeared to be no necessity for immediate surgical relief. The attack simulated rheumatism, which refused to yield to the usual treatment. The muscles and joints of both legs were involved, but the symptoms were not characteristic, and finally, in his search for an explanation, the physician, Dr. Sprigg, found the abscess under the cecum. Operation was performed on the sixth day at the patient's home, with the assistance of Dr. Sprigg. The abscess was evacuated, the appendix removed, and a second abscess found behind the peritoneum. The appendix was "south" in this case, and the conditions found were almost precisely as in the first case mentioned. The treatment was by transperitoneal drainage, and was continued for 5 weeks before a cure was effected.

In these cases we had to deal with a mild form of infection, and there were no dangerous symptoms at any time during the convalescence.

It is well, however, to reflect upon what would have happened had we not found the retroperitoneal infection at the time of operation. It is evident that such cases frequently occur, and in this manner is explained the long and tedious recoveries after "easy operations," and occasional burrowing of pus toward Poupart's ligament, or upward toward the diaphragm.

CASE IV.—Appendicitis associated with sepsis. Appendicectomy affords no relief. Thrombophlebitis and gangrene of cecum and ileum. Death.

*The method of Deaver and others who describe the location of the appendix and its general direction by using the points of the compass is an excellent one and we find it very satisfactory.

Mr. L., a medical student, aged 20, had one attack previous to July 5, 1901, when first seen by me with his family physician, Dr. Klipstein, in a neighboring city.

The patient had the usual symptoms of appendicitis, such as pain at the cecal point, with digestive disturbances, and added to these had typical sepsis, with rigors and sweats.

Our fears as to the patient's condition were not relieved by the operation. We found a gangrenous appendix, with enteroliths deeply buried in an abscess either in or under the mesentery of the cecum. The peritoneum was congested and thickened around the field of operation, but there was no diffuse peritonitis. There was, however, what we afterward found to be retroperitoneal infection. The mesentery of the cecum was thick and inelastic. It was with much difficulty that we raised the cecum sufficiently to reach the base of the appendix, in order to remove it and close the bowel. The indications were clear to open into the infected area, and perhaps make drainage through the loin or over the iliac crest. We erred here irretrievably, and lost our only opportunity to save the patient. Although our drainage was carefully placed by way of our incision over the cecum, nothing was accomplished by our operation. We should have opened up the retroperitoneal space through an incision over and in front of the crest of the ilium, and should have made careful search for the infected area. Not having done this, our patient went from bad to worse, without the least benefit from the intraperitoneal work. We feared to incise the peritoneum when we had the abdomen open. We were absolutely certain that we had a streptococcal and possibly a mixed infection to deal with, and this was finally demonstrated by bacteriologic examination. On the fifth day a fecal fistula was formed, and immediately after this came gangrene of the cecum and lower ileum, due to ileocolic phlebitis. The patient died of septicemia on the seventh day after operation, having had repeated chills and every symptom of profound toxemia.

The autopsy disclosed extensive postperitoneal cellulitis, with entire obliteration of the vessels supplying the region of the appendix (ileocolic arteries and veins). We were not allowed to extend our incision, or examine the liver or spleen. Cultures made from the retroperitoneal pus showed streptococcal mixed infection.

CASE V.—Septic appendicitis. Retroperitoneal infection. Primary and secondary operation. Death from sepsis.

B., a boy, aged 14, had his second attack of appendicitis in June, 1901. The attack was typical of appendicitis, with the addition of a chill and septic indications. The first consultation with the family physician, Dr. O. Leech, was held June 25, 1901. The boy was vigorous and previously healthy, and gave every evidence of being well able to bear operation, although he now appeared ill, and we saw unmistakable signs of systemic infection, which indicated, as in the preceding case, a very unfavorable prognosis. Operation was performed on the fifth day after his first symptoms. Repeated chills, high temperature, sweats and general malaise indicated extension of the infection to the lymph channels or retroperitoneal cellular tissue, and our operation gave no relief whatever. There were no signs of peritonitis. A small amount of pus was found when we removed a very soft and necrosed appendix. Indications pointed to retroperitoneal infection, and we resolved to make additional incisions if relief did not follow appendicectomy.

We made a second incision on the third day after operation, thinking we might discover pus in or under the mesentery of the ascending colon, and opened up the retroperitoneal space by pushing the peritoneum well forward until we were successful in evacuating a small abscess, located behind the mesentery of the cecum and adjoining ileum. Here we again hesitated to explore deeply, fearing to carry infection into healthy territory.

It was possible to raise the peritoneum from its bed or posterior attachments, and we could easily have extended our incision so as to reach the entire area between the vertebral column and the iliac fossa. We probably lost our only opportunity here. We did not succeed in reducing the high temperature or in affording any substantial relief to the patient who survived the second operation only 4 days. The autopsy was very imperfectly performed, being limited to an examination of the wound area through the incisions already made. We found the peritoneum dark, and, indeed, almost necrotic, on the mesenteric and posterior surfaces. A general or diffuse infection had spread rapidly from the mesentery of the cecum behind the peritoneum, causing all the bad symptoms presented by the patient. Here was a repetition of nearly every symptom shown in the preceding case, and while we were ready to go to the limit of our patient's strength, if necessary, in our next operation, still we were unsuccessful, as will be seen.

CASE VI.—The patient, who was sick 12 days, was subjected to operation for appendicitis. Abscess was discovered in the mesentery. General septicemia. Gangrene of intestines. Death in 3 weeks of thrombophlebitis and infection of retroperitoneal space.

Mr. D., aged 17, a fairly healthy lad with a history of one previous light attack of appendicitis, was taken ill in May, 1903, while in a distant city. His primary symptoms were clearly those of appendicitis, and an operation was proposed, but declined, as the patient seemed to improve. His pulse was but slightly accelerated, and his temperature not above 101° plus, at any time previous to his return home on May 30, 1903.

When seen by his family physician, a week after the first symptom, there were no signs of peritonitis, yet a small mass could be felt, which appeared to be an enlarged and adherent appendix. His temperature would drop down to normal on alternate days, and he was consequently subjected to antimalarial medication. He was seen in consultation with his physician, Dr. H. T. Harding, on the eleventh day of his illness, and operation set for the day following. We had no reason to fear the outcome of this operation. The patient had no serious symptoms of sepsis. His condition was most excellent, and not until the time of operation did we suspect infection of the mesentery.

Operation was performed on the twelfth day after the initial symptoms. The peritoneum everywhere appeared healthy. The appendix was covered over by the caput coli and ileum, which were firmly adherent. The base of the appendix was first discovered, and afterward the whole organ was located and removed, although it was so necrotic, and its appearance so much changed that it could scarcely be recognized. A small amount of pus was found around the appendix, and after a careful search another abscess of small size was found, which was carefully cleansed and sterilized. This abscess was situated in the mesentery immediately under the location of the appendix, which was northeast, or between the cecum and vertebral column. In close proximity to the abscess cavity, we found in the mesentery some rather interesting features, although not necessarily related to the present illness. Immediately under the location of the appendix, which was northeast and to the left of the cecum, and between its mesentery and the vertebral column, we found several greatly enlarged and calcified glands, which were in the mesentery of the lower ileum, and which gave to the finger the sensation of large enteroliths* which might have escaped from the bowel through the ruptured appendix.

An abscess was discovered behind the mesentery immediately upon the psoas muscle, and we made extraordinary efforts to deal carefully and thoroughly with the conditions found. Rather less than an ounce of pus was evacuated, after which a rubber drainage-tube was placed and secured in position with catgut sutures. This tube was placed in the cavity of the abscess, and it would have provided all necessary drainage if no other infections had started. The infected area about the cecum was packed with gauze, and we confidently expected to save our patient after our most careful and complete operation. Although the patient had been sick for 12 days, he was in good condition, and left the operating room with a good, although somewhat accelerated pulse (120 per minute).

The immediate effect of the operation was only fairly satisfactory. There were no symptoms of bowel obstruction or peritonitis at any time. A fecal fistula developed and then sloughing of the bowel began, shown by the discharge of large pieces of necrosed ileum. The patient's condition was one of severe sepsis, and we were obliged to content ourselves with the hope that his strength would continue until the force of the infection expended itself. Certainly no surgical relief appeared possible, and even with the lesson of this case with the autopsy, and the experience gained in treating the others mentioned, we fail to see how the fatal result could have been averted, unless extraordinary measures had been tried at the time of operation.

The autopsy was made soon after death, and revealed general extraperitoneal suppuration extending in every direction from the site of the abscess found at the time of the operation 3 weeks previous.

Fully 12 inches of ileum had sloughed, and of this, several inches had been discharged. Owing to the long-continued fecal discharge from the sloughing bowel, the peritoneum in the region of the wound, and below this point in the right side of the pelvis, was dark and almost gangrenous in appearance. By far the most interest, however, lies in the extent of the infection in the cellular tissue behind the peritoneum. The infection had reached to the right kidney, and indeed a considerable quantity of pus was found here. It appeared to have extended along the psoas muscle in the direction of the diaphragm, and we also noted the involvement of a considerable area over and to the left side of the vertebral column. The tissues removed for examination consisted of portions of the cecum and ileum, with the mesentery adjoining. Owing to careless methods, the specimen was not so carefully preserved and examined as we had hoped. Enough was seen, however, not only to disclose the cause of death, but to throw some light upon the extensive tissue changes found. The probable course of events was as follows: First, a tuberculous glandular disease, occurring in childhood, which was confined to the lymphatic glands within the mesentery. The calcareous condition had succeeded the "caseous stage." A cure was completed as the calcification was completed. Then, after one or more very slight attacks of appendicitis, the organ adhered in an upward direction, pointing "northeast," between the mesocolon and vertebral column, immediately over the calcified glands. Finally, a severe infection within the appendix caused a rupture at the distal extremity, and an abscess formed, with the resulting retroperitoneal infection. The gangrene of the gut

* These calcified glands were afterward examined and found to be of mesenteric origin, and their condition a result of former tuberculosis.

was due to infectious phlebitis, and probably arteritis, for we found sloughing of all that portion supplied by the ileocolic artery and veins.

CONCLUSIONS.

In our first 3 cases, the infection was probably due to one of the less active or destructive bacteria, as the clinical history was not marked by chills, sweats, etc., and without extension to distant organs or tissues. A streptococcal infection, for instance, would have caused far more serious results, such as pyelophlebitis, etc. The next two were due to streptococci, associated with other microorganisms, constituting a mixed infection, as shown by cultures made at the time. The last case was due to the colon bacillus, likewise mixed with other germs. Our patient had persistent fever with sweats, but without chills or rigors. Moreover, he continued his brave, although unsuccessful effort, against infection for 3 weeks after operation, while the streptococcal mixed cases succumbed in far less time.

Given the opportunity at the time of operation, we may, as in our first, second, and fourth cases, make provision for the inevitable retroperitoneal infection and suppuration. The question, then, is one of radical methods and abundant drainage. In our fatal cases there was need for postperitoneal drainage applied above or in front of the sacroiliac junction. The question arises, shall we in the future always provide such drainage at the time of operation, even at the cost of severe traumatism and prolonged operation? There is but one answer to this question. Sound surgical principles demand completed operation, and we do not believe an operation complete in all cases when the appendix is removed. It was impossible to drain successfully in all of our cases through the peritoneum. Drainage was fairly satisfactory while the tubes remained in position, but it is impossible to drain safely the retroperitoneal space by the transperitoneal route, and it is obviously better to attempt such drainage from behind. The anatomic formation of the retroperitoneal space renders successful drainage rather difficult and occasionally impossible. It is, however, of the utmost importance to expose fully any infected region behind the peritoneum if the symptoms preceding the operation, and the pathologic changes found at the time of operation, plainly indicate retroperitoneal infection. The retroperitoneal space at this point is one of greatest interest and importance, for here we not only have mesenteric vessels, but lymphatics, and the thoracic duct is not far distant.

When we suspect retrocecal or retroperitoneal infection as a complication of appendicitis, we should, as a rule, make a careful search for the infected area, and provide drainage by the posterior route, whenever practicable. When postcecal, the incision must be ileolumbar and the peritoneum pressed forward, much as when one exposes the ureter. In all cases in which we have to deal with infection of the mesentery of the cecum, we will find it possible to reach this area through the incision named, especially when suppuration has begun. When the abscess lies under an appendix, "east" or "south" of the cecum, we may have greater difficulty in reaching the seat of infection, but this entire region is to be searched for induration or commencing suppuration, before we are justified in abandoning a patient to the perils of septicemia. If suppuration has begun, it will invariably be much easier to locate the pus, even if very near the vertebral column, in which case we would be compelled to expose the mesenteric vessels supplying the cecum. In our cases we found it far easier to open this space than we had expected, and we purpose to continue our search in future for retroperitoneal infection along these lines. We may yet learn to discover retroperitoneal infection at the time we usually operate for appendicitis. Indeed, this is our

earnest wish, that we may be able to check this form of infection before its ravages have extended beyond our reach. It appears a plain duty in certain septic cases to investigate the retroperitoneal space with the same care as the cavity of the peritoneum.

1. We should consider every "delayed case" with anxiety, lest there should be retroperitoneal infection.

2. We should be careful to give a guarded prognosis in every case of appendicitis ushered in by, or complicated by chills or any symptoms of sepsis.

3. If operating in such cases, we should consider retroperitoneal infection as already started and act accordingly. The discovery and proper treatment of such infection is quite as important as the usual intraperitoneal technic.

In view of the possibilities of retroperitoneal infection, we assume a great responsibility by advising non-intervention in appendicitis, and while we often advise delay when we believe the lesions strictly intraperitoneal, yet it would appear that such a course is very unsafe and it should be condemned when we have reason to fear the complications described.

"URETHRAL LABIA," OR "URETHRAL HYMEN" PATHOLOGIC STRUCTURES, DUE TO REPEATED TRACTION.

BY

ROBERT L. DICKINSON, M.D.,
of New York City.

In *American Medicine* of September 12 and 19, Dr. Howard A. Kelly describes and depicts in his graphic manner those tiny projections about the meatus first fully published and pictured by me, in *American Gynecology* for September, 1902. Kelly believes that their function is "undoubtedly protective, serving to keep the delicate urethral mucosa with its glands from a constant exposure to leukorrheal discharges and the bacterial flora of the vaginal outlet." "These labia," he goes on to say, "also form an important part of the sexual apparatus, as they are impinged upon and in cases of disease are more liable to insult than any other part of the genital tract. This observation applies with special force in cases in which the levator ani is unimpaired and in which the soft subpubic tissues form a barrier which has to be overcome."

Whatever causes the introitus to gape throws the meatus wide open and exposes to view and to contact, to friction and to "insult," the prominent openings of the urethral glands (the glands of Skene) which end on the inner surfaces of these thickened lips of the meatus.

Figs. 2, 3 and 4.—The extreme form of development of urethral labia, flanking dilated urethra. This meatus admits the finger-tip; on each side the opening of the urethral gland is at the summit of a prominence which is seen to be continuous with the hymen; the latter admits the smallest Sims' speculum. When closed, this hymen looks normal. The vestibular V shows faintly. The diagram exhibits the shape of the hymen, and the location of openings of Skene's glands.

Therefore, these outspread wings are crushed against the sharp lower edge of the subpubic ligament, to and fro, with no little force, either in coitus or manipulation. Indeed, the meatus is largely endowed with special

sensibility. When a vulva of moderate size is distended by a Sim's speculum, large or small, the urethral lips open widely.

Far from being natural barriers, these prominences are entirely artificial and pathologic. *Hypertrophy about the meatus occurs only when there are hypertrophies of the labia minora, the clear-cut evidences of traction, pressure, or friction.* They are to be detected in 20% of such cases, and are to be distinguished from swellings caused by inflammation or infection. The drag on the meatus, or its pressure backward and forward across the subpubic arch and the face of the pubes, produces this elongation of the lips of the meatus. The V-shaped ridges

Figs. 5 and 6.—Hymen of a parous woman, torn near fossa navicularis (FN). Its anterior sweep is seen to pass beneath (dorsal to) the meatus (M), and one ear is turned forward. No glands are to be found. The diagram shows the form of this hymen. Fig. 7.—A very thick hymen, just admitting one finger, the meatus on its anterior edge. Here the urethral labia are evidently forward prolongations of the hymen.

of the vestibule running up from the meatus to end beneath the clitoris furnish further evidence of such traction. This vestibular V is found in about half the cases with urethral lips.

Prolonged congestions and repeated slight edemas

Fig. 8.—The glands run into the anterior columns of the vagina when enlarged. Figs. 9 and 10.—Extreme form of enlargement, life size. Solid projections with large glands. The meatus admits the finger freely. Incontinence, urethral friction. Fig. 11.—The sole remnant of hymen this multipara possesses is fast to the urethral labia.

will explain the cases which exhibit thickening without much elongation, as shown in Fig. 9. Such is likewise the explanation of thickening of the labia minora—thickening, as distinguished from elongation and wrinkling. To the touch the two prominences are often conspicuous, firm, rounded, protruding.

As a further argument that the lateral tabs are no successful barriers against infection, attention is drawn to the frequency of pus discharge from the big and deep urethral glands which I have shown to belong with the hypertrophied lips of the meatus.

As to their anatomic geography, these urethral labia seem to me to be the hypertrophied anterior part of the hymen. When the hymen is thickened and pouting

(whether tiny in opening or wide), the anterior folds of it can be seen to be continuous with the lips of the meatus. Herein the cuts illustrating Kelly's article are carelessly drawn and untrue. (Compare them with my Fig. 18, in *American Gynecology*, September, 1902.) They are also defective as complete observations in the instances in which the labia minora have been hastily sketched in (Figs. 1, 5, and 7), but Kelly's Figs. 2, 3, and 9, rightly show enlarged corrugated labia (or the relaxed atrophy of subsiding enlargement). Yet in November, 1901, at Johns Hopkins, I showed Dr. Kelly,

Mr. Brödel, and Mr. Becker the flaps of the meatus and stated to them the cause of this peculiar little alteration.

It will often appear that these tabs are hypertrophied outer ends of the urethral glands. The pockets often open at the very apex of the ear-like flaps, but also may be found at their base. Exceptionally, no urethral gland can be detected in large flaps, even with the filiform bougie.

In my paper referred to in the foregoing, the following statements are made:

The meatus is usually triangular in shape, the sides of the triangle curving inward, the apex toward the clitoris. The posterior side frequently bears a notch or dip at its center. On this rear side near each outer angle the openings of the urethral glands are usually found, though their location varies considerably. At these lower outer angles, in our cases of hypertrophy, a curious pair of flaps or tabs was noted in about 20% of the list.* At times pyramidal and broad of base, merging into the anterior fold of the hymen on the rear or vaginal side; at times thick or crescentic, and again pointed or earlike, these protrusions lie

against the sides of the meatus, or point toward the clitoris, and it is only by drawing the hymen open, or the meatus well apart, that their shape is developed, often projecting 2 mm. to 5 mm. I have seen protrusions 7 mm. thick at the base, 20 mm. in height, looking almost like tiny nymphs. Just within (at times without) the apex of each flap the opening of a urethral or Skene's gland is found. A filiform bougie or fine silver probe develops the fact that the gland is much longer than normal, often running downward and backward into the anterior

puration in the urethral glands is not infrequent. The openings may gape, reddened and tender. In advanced cases of the vaginal habit the meatus will admit the tip of the little finger for a short distance and without discomfort. In others, the opening gapes, the orifice of the Skene glands marking the outer angles. In the worst instances, the flaps stand out on each side of a gaping slit. In all a complete lack of sensitiveness within the meatus for at least half an inch is notable. The Kelly cystoscope No. 14 goes in through the lower half with ease. In 2 cases incontinence was present. In both these instances the vulva and vagina had evidently been exhausted as locations for producing sensation. The urethra then was the only new surface remaining.

The hypertrophies which I here picture seem to be clearly explained by Pozzi's view of the origin of the hymen, which is opposed to the commonly accepted theory advanced, especially by Henle and Budin (Pozzi "Traité de Gynécologie," Second Edition, page 1088):

The development of the hymen is of late occurrence in the embryo. Not until the nineteenth week do we see appear a sort of fold about the uterovaginal conduit at the anterior orifice of

Figs. 12 to 15.—Four sketches of a virgin hymen that protrudes like that of a newborn child; the urethral opening in the upper half of the hymen nearly as large as the vaginal opening in the rear half of this hymen. Diagram of relations: M, meatus; H, hymen; V, vagina.

Figs. 23, 24, 25 and 26.—The enlargement produced by inflammation and infection alone, without traction, (23) in which one side is affected; (24) in which both glands are swollen; (25) in which three openings are exuding pus; (26) thickening from chronic inflammation of both glands. Fig. 27.—Abscess of one Skene gland, displacing the urethral labium of the left side outward. Here the labia form a complete circle about the meatus. Virgin of 17.

the vaginal canal, which is formed above by the fusion of Müller's ducts and below by the vestibular canal, the latter the vestige of the urogenital sinus. At first there are two linear elevations, which advance toward the median line until they meet. For the time being the hymen is a double organ and the little ribbon (bandelette) which it forms on each side of the urogenital fissure is continued beyond the opening of the urethra up toward the base of the clitoris. When the vulvar and urethral orifices are formed, it incloses (frames) both of these openings, forming about the first-named the collarette of the hymen and about the latter an annular ridge, very conspicuous in children, continuous below with the hymen, and above with a median prominence, which is analogous to the frenum of masculine hypospadias. Thus constituted, the hymeneal apparatus is composed of three portions: 1. Hymen. 2. The annular prominence which surrounds the urinary meatus (bourrelet du méat), sometimes so pronounced as to merit the name *urethral hymen*. 3. The masculine bridle (or frenum) of the vestibule. Anomalies of development may affect these three segments, and their solidarity, hitherto unsuspected, enables us to explain readily a number of facts.

Dr. Kelly elaborates seven methods of treatment—

emptying, massage, injections, incisions, dissection, and the cautery. A protest should be registered by a pupil and associate of Dr. Skene against wasting time on any other method than the swift and efficient one used by the man whose name is coupled with these tiny, but troublesome structures: The mouth of the gland and the vestibule and anterior vaginal wall below it are cocainized; a probe is passed from above into the gland to its deepest point, and the point of the probe swung toward the operator, so that the tissues show tense and thin over

Fig. 16.—Hymen and its anterior tabs in a girl. Fig. 17.—Another form of the same. The urethra may be above the lips or between them. Fig. 18.—Hymen with urethral labia in a married woman. Fig. 19.—Hymen with urethral labia in a parous woman. Fig. 20.—Hymen with urethral labia in a nullipara. Fig. 21.—The meatus within the sweep of the forward part of the hymen. One gland, the right, is swollen and pouting. Virgin. Fig. 22.—A frequent form of projection; in this case, with no openings. Fig. 22a.—Pendulous urethral tab on each side of a dilated urethra. This is atrophy, a later stage than Fig. 22.

column of the vagina. Several gland openings may be seen. This anterior end of the hymen may be the only part of that structure which has undergone alteration; its folds are thick and a prominent ridge connects directly with the meatus flaps, as shown in the diagram. Two diverging ridges sometimes run forward from the meatus.

Three forms of alteration at the meatus have been noted, namely, dilatation, dilation with and dilation without hypertrophy. Varicosity, prolapse of the mucous lining of the urethra or caruncle may be present. Inflammation, catarrh, or sup-

the probe. Against this stretched white line the hot electric cautery needle or knife is laid. A second suffices. The wound granulates with no further care. This is surely better than 28 injections, or even than 8 injections by which Kelly reports patients cured. The less manipulation of this peculiarly sensitive region, the better. If any injection is to be used, argyrol in 20% solution is painless and powerful, and carbolic acid in full strength hurts but a moment. Dr. Kelly's combination of tubing and needle is simple and efficient. The paquelin cautery knives are not delicate enough for this work.

* Waldeyer, *Das Becken*, 1899, p. 560, says these ledges and lapels hang out of the urethra with the folds of the urethral mucous membrane.

Summary.—The urethral labia are hypertrophies produced by oft-repeated traction, and are only found in company with hypertrophied nymphas. They are enlargements of the anterior portion of the hymen.

Fig. 28.—Dilation of the urethra without enlargement of the glands and without urethral labia. The openings of the glands are plainly visible. Nullipara. Fig. 29.—Operation for obliteration of diseased gland. The probe renders the tissues tense, the cautery knife severs them.

Long urethral glands ordinarily course through these flaps. They have no protective function, but are connected with special sense. The only certain method of cure is section with the cautery wire.

A NEW TECHNIC IN OPERATIONS FOR APPENDICITIS.

BY

W. EASTERLY ASHTON, M.D.,

of Philadelphia.

Professor of Gynecology in the Medico-Chirurgical College of Philadelphia.

In performing an appendicectomy there is always danger of infecting the parts surrounding the seat of operation when the appendix is amputated and the opening in the gut is sutured. The reason for this is evident, and is due to the operator's fingers and the

this cause. It could hardly be otherwise when we consider the usual methods employed in the technic of the operation, as there is constant danger of touching the septic mucous membrane with the fingers or the instruments when the head of the colon is held between

Fig. 2.—The pursestring suture and the control ligatures are in position beyond the base of the appendix, which is held taut by the assistant.

the thumb and the index finger of the left hand during the introduction of the sutures to close the opening in the bowel. Again, the head of the colon may slip from the grasp of the operator's fingers during the process of

Fig. 3.—All the control ligatures are held taut, and the head of the colon is within the abdominal wound.

suturing, and before it can be brought into position again, the surrounding intestines may come in contact with the opening in the bowel and become infected.

The practical importance of an operative technic which reduces to a minimum the danger of direct infection during the necessary manipulations of an appendi-

Fig. 1.—The head of the colon is within the abdominal wound and the mesoappendix is ligated and severed. The control ligature is tied around the tip of the appendix and held taut by the assistant.

instruments coming in contact with the exposed intestinal mucous membrane at the seat of amputation.

Many of the unexpected deaths which follow operative interference in uncomplicated cases of appendicitis, as well as the chronic sinuses and the delayed recoveries which result, are undoubtedly due to an infection from

Fig. 4.—The gauze packing is being placed around the head of the colon.

ectomy cannot be overestimated, and with this object in view I have devised the following method, which I have employed for several years.

The technic which I shall now describe deals entirely

with the amputation of the appendix and the subsequent closure of the opening in the colon; the other steps of the operation being similar to those generally employed. My method gives the surgeon complete mechanical control of the colon, and prevents his fingers or the intestines from becoming infected, as the appendix can be amputated and the opening in the bowel sutured without the operator touching the seat of operation. The method may be conveniently described under the following steps:

First Step.—After the appendix has been located and freed from adhesions, the head of the colon is brought within the

Fig. 5.—The gauze packing is completed and the circular incision is being made through the serous coat of the appendix.

abdominal incision. A No. 7 braided silk ligature is then tied around the tip of the appendix, the free ends knotted and the loop, which should be about 6 inches long, is held taut by the assistant.

Second Step.—A ligature of the same material is now passed through all the coats of the colon, except the mucous, about three-quarters of an inch beyond each side of the base of the appendix. The free ends of the ligatures are then tied, leaving 2 loops, each 6 inches long, which are used to control the head of the bowel. A pursestring suture is now passed through all the coats of the bowel, except the mucous, about a half inch from the base of the appendix.

Third Step.—The appendix and head of the colon are now completely under the control of the operator, who keeps the appendix taut by traction upon the ligature, which is tied

Fig. 6.—The serous coat is stripped back beyond the base of the appendix.

around its tip. At the same time the assistant grasps the loop on each side of the base of the appendix, and by making traction upon them holds the head of the colon well within the abdominal incision.

Fourth Step.—The seat of operation is now shut off from the surrounding parts by packing a strip of plain gauze around the head of the colon.

Fifth Step.—The mesoappendix having been previously ligated and severed, a circular incision is made through the serous coat of the appendix about a half inch above its base.

Sixth Step.—The peritoneum is then stripped back beyond the base of the appendix with the scalpel.

Seventh Step.—The appendix is now amputated below its base with scissors curved on the flat.

Eighth Step.—The opening in the bowel is now closed by inverting its edges with forceps as the pursestring suture is tied, and subsequently introducing a mattress suture to guard against leakage.

Ninth Step.—The operator now douches the seat of the operation with warm normal salt solution, and dries the parts with a gauze sponge. The gauze packing is then removed; the control ligatures cut and withdrawn from the bowel; and the head of the colon allowed to sink into the abdominal cavity.

Special Directions.—The control ligatures which pass

Fig. 7.—The appendix is being amputated beyond its base.

through the walls of the colon on either side of the base of the appendix must penetrate only the submucous or fibrous coat, because if they enter the lumen of the gut, infection may result from capillary attraction.

From the time the appendix is amputated until the opening in the colon is sutured and the field of operation douched and dried, the assistant must keep the control ligatures taut to

Fig. 8.—The pursestring suture is being drawn taut while the edges of the wound are inverted with forceps.

prevent the bowel from becoming displaced and infecting the surrounding intestines.

The serous coat of the appendix must be stripped off well below its base so that when it is amputated a portion of the wall of the colon is also removed. This not only thoroughly eradicates all the diseased structures, but it also leaves no redundant tissue to interfere with the close approximation of the edges of

Fig. 9.—The cecal wound is completely closed by the pursestring suture. The mattress suture, which is introduced to reinforce the approximation of the edges of the wound, is not shown in the illustration.

the wound. As a matter of fact, under these circumstances, the serous coat usually retracts and partially closes the opening before the pursestring suture is drawn taut. The antiseptic precautions employed during the operation must be thoroughly carried out, as we are necessarily dealing with an open wound of the intestine. Therefore all instruments which come in contact with the seat of operation must be thrown aside at once, and not used again. Thus the knife which is employed to make the circular incision through the serous coat, and

the scissors used to amputate the appendix, naturally become infected, and must be discarded at once. A serious mistake is often made from an antiseptic standpoint in operations of this character by using the same sponge several times on the seat of operation. This habit undoubtedly spreads infection, and often causes postoperative complications which can easily be avoided. A sponge which has been pressed once against the tissues should be discarded and not used again. If this is not done the pathogenic germs which adhere to the sponge will be scattered over the uninfected areas surrounding the field of operation. In an aseptic field, this precaution is, of course, unnecessary, but when as in an appendectomy the

Fig. 10.—Cushing's suture is being introduced. The assistant is making traction on the head of the colon while the surgeon steadies the field of operation with the upper control ligature.

sponge comes in contact with the contents of the intestinal canal, it is obviously a dangerous practice, and one which must result in jeopardy to the life of the patient.

Variation in the Technic.—If for any reason a pursestring suture cannot be used to close the opening in the colon, a Lembert or a Cushing suture may be substituted. The first 6 steps of the operation are the same as described above, and after amputating the appendix, the surgeon then grasps the upper control ligature about an inch from the bowel with the fingers of his left hand to steady the field of operation while the wound is being closed. The sutures are introduced with a small, full curved intestinal needle, which must be held in the grasp of a needle-holder or a hemostatic forceps.

THE PATHOLOGY OF LEUKEMIA.

BY

EDWARD T. WILLIAMS, M.D.,

of Boston, Mass.

The disease inaccurately designated by Virchow as leukemia, more accurately but not more rationally by Bennett as leukocythemia, may be clinically regarded as an organic leukocytosis. But the leukocytosis is merely a symptom, not the disease itself. The true disease is a leukosis, or white-cell hyperplasia, of one or more of the organs or tissues which make the white blood cells, namely, the bone marrow, lymph-glands, and spleen.

In another publication¹ I have attempted to divide the white blood cells or leukocytes into 2 classes, myelocytes and lymphocytes.

The myelocytes are all formed in the bone marrow, though differing widely in appearance according to their age and stage of growth. The youngest form is a large, nongranular cell, with a slightly acid (basophile) protoplasm, and a single oval or bean-shaped, faintly staining nucleus, usually excentrically placed. As they grow older, the protoplasm loses its acidity and acquires a partiality for neutral dyes. It also becomes finely granular. At the same time the nucleus becomes more and more divided, passing through various transitional stages till it finally assumes the shape of a multiform (polymorphus) nucleus. These changes may take place either in the marrow or the blood into which these cells are perpetually passing. Such is the origin of the multinuclear leukocyte.

These cells are also liable to another change, which may be classed either as a necrosis or a necrobiosis. The process always begins with a dissolution of the nucleus (karyolysis), which gradually loses its chromatin, becomes paler, acquires a hazy outline, and discharges the products of its decomposition, the nuclein bases, in a

liquid state into the surrounding cytoplasm, where they are precipitated (as observed by Tettenhamer) in the form of alkaline drops, the so-called eosinophile granules. Such, in all probability, is the origin of the eosinophile leukocytes.

I contend that all these variations are simply different stages in the growth, development, and decay of one species of cell, the myelocyte.

The lymphocytes, on the other hand, are small cells with a single nucleus, surrounded by a narrow rim of strongly acid (basophile) protoplasm. They originate mainly in the lymph-glands, whence their name, though also found in smaller numbers in the spleen and marrow.

Now, as there are 2 distinct forms of leukocytes, originating respectively in the marrow and lymph-glands, pathology shows us that there are also 2 distinct forms of leukemia, according as the primary disease (leukosis) is seated in the marrow or glands.

In medullary leukemia, the commoner of the 2 forms, the primary disease is in the marrow. The red marrow loses its color and becomes whitish, or, as the Germans say, pus-like (pyoid). Under the microscope we find a marked hyperplasia of marrow cells of all types. The eosinophiles particularly are present in large numbers. Among these are numerous spermin crystals, the common products of decomposing nuclein. The red corpuscles are diminished in number, with an unusual preponderance of erythroblasts, as in organic (pernicious) anemia. Secondary deposits of the same character are commonly found in the spleen and lymph-glands, and often in the liver, kidneys, lungs, and other organs. The blood is always surcharged with the same elements.

Lymphatic leukemia is a rarer disease, and differs essentially from that just described. The primary affection is in the lymph-glands. We find these glands enlarged, whitish or greyish-white on section, and overloaded with lymphocytes. Many of these are decidedly larger than usual, but are all of the same type. We never find any form of marrow cells or eosinophiles in pure lymphatic leukemia. Secondary deposits of a similar character are regularly found in the spleen and marrow, and sometimes in other organs. The blood is surcharged with lymphocytes, great and small.

These facts seem absolutely incompatible with any other theory than that of the duality of the leukocytes. The dual character of the disease corresponds precisely with the dual division of the cells into the medullary and lymphatic types. The connection is complete and points unmistakably to the true nature of the processes involved. Thus pathology confirms the teachings of physiology, and physiology simplifies and rationalizes pathology.

THE TREATMENT OF CERVICAL ADENITIS.

BY

F. S. BULKELEY, M.D.,

of Ayer, Mass.

In all the literature to which I have had access, the treatment of cervical adenitis has been, in my opinion, incompletely covered in at least one detail—treatment with avoidance of scar, or to obtain the minimum of scar. Suppuration having arisen, the question of surgical interference confronts us, and the only method I have seen mentioned to avoid a bad scar is to plan the incision to take advantage of the natural skin creases. While this certainly should be done, it may be possible, in some cases, to go even further.

For the purpose of treatment, I will divide cases of adenitis as follows:

A. Cases in which the severity or the location of the infection and the symptoms resulting therefrom may seem a menace to life, or in which some complication calling for active interference has arisen. B. Tuberculous glands. C. Cases in which immediate radical inter-

¹ Williams: Studies on the Leukocytes, Boston, 1903.

vention is not demanded, and in which the avoidance or minimizing of scar may be of great importance to the patient.

(a) The first class has, in my experience at least, proved relatively infrequent. Examples of it are found in some cases of adenitis involving glands under the deep cervical fascia and in close proximity to the great vessels of the neck, in cases causing brawny induration of the whole side of the neck, or in cases with active hemorrhage into the abscess cavity. In such cases the question of resulting scar becomes of secondary importance, and the more radical surgical measures must be adopted. In fact, some of the expedients I shall speak of would subject the patients to considerable risk. I wish to omit this class from further discussion.

(b) In cases of tuberculous glands, early treatment is of greatest importance. The various general measures of use in tuberculous affections are too well known to demand detailing. Hygienic measures should be taken. All the areas drained by the affected glands should be inspected and treated as may be indicated, particular attention being paid to the nose, mouth, and throat. The tonsils should be carefully investigated, and any abnormal condition present in the nasopharynx should be remedied. A careful regulation, or rather supervision, of diet may be called for in some cases. Perhaps the majority of such cases occur in children with weak digestion, and great care should be taken not to upset a digestive tract already weak. Iodid of iron and cod-liver oil are perhaps the most useful of the internal remedies, but care must be exercised in giving them. In my experience it has proved the better plan to begin with small doses and to increase them gradually to the point of tolerance, continuing their use at a dose slightly under that. Many other drugs may be useful, other forms of iron, potassium iodid, arsenic, etc. Medical indications are to correct any other abnormality present, as anemia, and to build up the system. Local treatment should be the same as in any case of inflammatory adenitis. In the early stages hot fomentations may prevent suppuration. Kellogg recommends the use of alternate hot and cold compresses for a short time several times daily.¹ As a general rule, before pus has formed, applications should be hot or decidedly cold. A poultice that is simply warm will favor hyperemia and the formation of pus, while one that is distinctly hot will cause contraction of vessels and may check a developing inflammation;² cold may prove useful, and the ice-bag, judiciously used, is perhaps one of the best means at our disposal. Pus having formed, cold applications may be used, particularly if the skin is reddened; or if we wish to hasten pointing we may use a warm poultice. A large number of drugs are used as local applications, among which may be mentioned iodine and ichthyol. Both have been credited with specific powers in causing absorption, but it is doubtful if they possess them to any great extent;³ their main value is as counterirritants; in my hands neither has had decided effects. Antiphlogistin, in some cases, works well, but probably does so because it is applied hot. Iodine as a vasogen preparation has the advantage of not staining the skin. Injection of a few drops of dilute carbolic acid into the substance of the gland is recommended, but is said to carry the danger of the formation of a slough. I have had no experience with it.

Radical operative interference in cases of tuberculous glands has been advocated and disapproved. In many cases of tuberculous adenitis no further trouble arises—the swelling subsides, and no other manifestation of tubercle bacilli is seen. But in other cases the adenitis proves to be simply the first of a train of tuberculous lesions. The claim has been made that tuberculosis of the lymph-glands has a protective influence against tubercle bacilli in later life, but I do not think the facts bear out this statement. Of course we see

many perfectly healthy adults who suffered from adenitis, apparently tuberculous in origin, in childhood, but this would seem only to prove them persons of high resisting power; for in many, tuberculous adenitis simply proves the first of a train of tuberculous lesions. Such cases are too frequent to seem simply a coincidence, and it seems very probable that the infection spreads from the glands first involved. However, it is not always possible to say that the trouble in the glands was the first tuberculous lesion, but in many cases it is the first clinical manifestation. Osler says that in three-fourths of the cases of acute tuberculosis the infection spreads from an infected gland.⁴ Infection of glands in the mediastinum may result, the caseation and rupture of which might prove very serious. The safer course to take seems to be that of radical treatment, and in cases not yielding to medical measures it should be resorted to. As to the choice of operative procedures, curetting and excision are the methods most highly recommended. The advantages of curetting are the ease with which it may be done, the small amount of resulting shock, and the comparatively small scar left, while against it are the facts that the operator cannot be as certain of removing all tuberculous tissue, and failing in this a sinus may result. The risk of dissemination of tubercle bacilli is considerable. If many glands are involved, scraping may fail to reach them all, and in deeply seated glands it is not safe. In many cases curetting is not applicable.⁵ Excision is the more difficult operation to perform, of greater severity, and leaves a larger scar. There is some danger of injuring important structures. Excision is applicable to nearly every case, is much more thorough, and attended with very little risk of dissemination of tubercle bacilli. In certain cases, in which the glands are too thoroughly broken down to make it seem feasible to attempt to dissect them out, curetting may be resorted to, but we should not allow the glands to reach this condition. Other things being equal, excision, done reasonably early, is the method of choice in cases not yielding to medical measures. It must be done with great care, and avoidance of haste is imperative. Sutcliffe calls our attention to some of the results of nerve injury⁶ and it should be made the rule to suture the ends of any important nerves divided; or, rather, the rule should be to take such care that none will need to be sutured. The question of ligature of the jugular in any case is one that must be decided when the peculiar conditions of the case are seen at operation, but it should be avoided if possible.

The avoidance of scar in group C is what I wish to emphasize particularly. A detail of primary importance in treatment is, of course, the removal of any source of irritation in the area drained by the glands. Treatment of the tonsils is very important. Goodale reports excellent results in cases of chronic cervical adenitis from the injection of iodine into the tonsillar crypts. Rogers reports a series of cases in which enlarged tonsils were removed to remedy a chronic adenitis with good results;⁷ he also says that tonsils with a normal appearance may contain a source of infection. I have had no experience with this plan of treatment; however, in my opinion, removal of the tonsils should not be first tried, but Goodale's suggestion of the injection of iodine or burning out the crypts with the electrocautery should be tried. Attention should be paid to the general health of the patient, and any measures indicated for its improvement should be taken. Very much the same drugs as in the case of tuberculous glands may be used. Local treatment should be the same, but even more care should be taken of the condition of the skin, in view of procedures that may be called for later. Very careful observation should be made of the gland or glands from day to day, for if fluctuation arises the plan of treatment must be changed somewhat, and the

question of how to avoid or minimize a possible scar confronts the attendant. The more radical surgical measures leave a scar that is very noticeable, or, it may be, disfiguring, and in some patients a bad scar may be the most disagreeable element in the trouble. There are several methods that may help to avoid a bad scar, all of which may be used singly or one after the other: Aspiration of the pus through a hypodermic needle of large caliber with or without subsequent injection of antiseptics, or the use of a seton. In bringing these measures forward, I do not uphold them as a means of certain avoidance of scar, but offer them as a resource that may be found valuable. Both failing we can resort to incision, with a plastic operation on the scar left after healing has taken place—thus obtaining a linear scar that certainly would be smaller than that following extirpation of the glands.

The technic of aspiration and the use of a seton are too simple to call for much description. In the former a hypodermic syringe with a needle of large caliber is sterilized, and after cleansing the skin, the needle is plunged into the point of greatest fluctuation. As much pus as can be obtained is withdrawn, and the syringe unscrewed, leaving the needle *in situ*. If the attendant desires to inject an antiseptic it can be done before withdrawing the needle. In the cases of which I have knowledge, both plans have been used, with the better results in the cases in which an antiseptic was used. In my hands the best results have followed the use of hydrogen dioxid. In 1 case both iodine and hydrogen dioxid were used separately, and the results with the dioxid were much better. The amount injected must vary with the size of the cavity, and must be decreased as the cavity grows smaller. Moderate distention is the result desired. In every case, after injecting the antiseptic, as much as possible is withdrawn; in spite of repeated trials some will remain in, but this proves of benefit. Both iodine and hydrogen dioxid act well. I have used a 10% to 30% mixture of the U. S. P. tincture of iodine in sterile water, and hydrogen dioxid in 50% strength. Aspiration may have to be repeated many times, and a new spot should be chosen for the puncture each time. The appearance of the fluid withdrawn, the size of the swelling, and the amount of fluid apparently present are the points upon which the necessity of aspiration is decided. It should be continued at suitable intervals until the fluid withdrawn is clearly nonpurulent, and it may be well to use the microscope to decide.

In some cases the pain caused by introducing the needle is considerable, but the use of an ethyl chlorid spray will make it bearable. Injection of an antiseptic will cause some discomfort, the amount depending upon the strength used. Hydrogen dioxid causes much less pain than iodine, and the amount of pain with either seems to depend partly on the degree to which the cavity is distended. The most obvious objections to this plan of treatment are the facts that the pus may be too thick to aspirate to any great extent, and that we may have multiple abscess cavities to deal with. In the first instance, it will be found that the injection of an antiseptic will disintegrate the pus so that it can be obtained at a later trial. If there are multiple abscess cavities they may be treated by multiple punctures, and it has seemed to me that the withdrawal of pus from one cavity followed by the injection of an antiseptic has had a favorable influence on adjoining cavities. For a local application while the foregoing treatment is being carried out I prefer a cold compress. This treatment failing or proving too painful for the patient, we may resort to the use of a seton. The gland is transfixed with a full curved needle carrying a coarse thread, either silk or cotton, which is drawn through and tied loosely. Other material may be used as a seton, but these two have proved themselves most acceptable to me. I should prefer to aspirate at least once before putting in a seton, to make sure that the pus is thin enough to drain easily,

although the seton has been used with good results as the first method adopted. The thread should be moved several times daily to prevent granulation tissue growing into its meshes. If the pus drains freely a warm poultice may be used to hasten the process, but if drainage is not free I should prefer not to use it. If drainage is not spontaneous the pus may be forced out by pressure on the gland. Of course, this method would leave two tiny scars, but they are barely perceptible as a rule, and the scars following the treatment by aspiration can be found only by looking closely, if indeed, any marks can be found. The length of time the seton is left in must vary in different cases, the clinical aspects of the case deciding it. In some cases it may seem as if abscess cavities were present that the seton did not drain. If this is the case, we may aspirate the cavity or we may put in a new seton, and it will be found possible in some cases to utilize one of the holes occupied by the old seton in introducing a new one. These methods may prove very tedious to the patient and the attendant may be forced to abandon them, but if this is the case treatment by incision is still possible. In the majority of cases even a short trial of aspiration or the use of a seton will reduce the size of the gland considerably, and incision after their use would not leave as large a scar as it would if done earlier in the course of the trouble. A very simple plastic operation after healing has taken place would produce a minute linear scar as an end-result.

SUMMARY.

1. Many cases of cervical adenitis will be seen in which the avoidance or minimizing of scar is of great importance, and in which radical operative measures are not demanded. In such cases aspiration, or the use of a seton, or both, while not infallible, may prove successful.
2. While such measures might be successful in cases of tuberculous glands they are attended with possible dangers, and when the tuberculous glands do not subside under medical treatment, excision, done with extreme care and reasonably early, is the method of choice.
3. Neither aspiration nor the use of a seton should be resorted to in cases involving the deep cervical glands.

In conclusion I wish to thank Dr. B. H. Hartwell, of Ayer, Mass., and Dr. Walter C. Howe, of Boston, Mass. Many of the foregoing suggestions are the result of their help and courtesy.

Effects of the Use of Alcohol.—The committee of 50 scientists which has for 10 years been studying the liquor question, has issued its fourth preliminary report in 2 volumes. The following are the main conclusions drawn: Effects of moderate or occasional use of alcoholic drinks differ with individuals, age, occupation, and climate. With the majority of occasional and moderate drinkers no special effect upon health seems to be observed by themselves or their physicians. In some such cases drinking is harmful; in a few it is thought to be beneficial. Eighty percent of the leading brain workers of the United States use alcoholic drinks occasionally or regularly or in moderation. The use of such drinks to stimulate mental effort gives, on the whole, bad results. Even occasional or moderate use is likely to be harmful to young persons, mainly because of the danger of its leading to excess. Among diseased or infirm persons over 50 years of age, alcoholic beverages, while sometimes useful, should be taken, if at all, with the last meal of the day. "Fine old whiskies" and "fine old brandies" are nearly as likely to produce injurious effects as are the cheaper sorts, if taken in the same quantities. In moderate quantities, beer, wine, and diluted whisky have a certain food value, but they are seldom used for food purposes—rather for their effects on the brain. In large quantities, and for some persons even in moderate quantities, they are poison. Alcoholic drinks in moderate quantities may be useful as restoratives in fatigue after work is done, but they often produce depression and harmful results when used just before and during labor, physical or mental.—[*Harper's Weekly*.]

A REPORT ON HEMORRHAGIC SEPTICEMIA IN ANIMALS IN THE PHILIPPINE ISLANDS.

BY

PAUL G. WOOLLEY, M.D.,
of Manila, P. I.

Pathologist, Biologic Laboratory.

AND

J. W. JOBLING, M.D.,
Director of the Serum Laboratory.

The appearance of hemorrhagic septicemia in the Philippine Islands was a serious complication of the local cattle problem. Rinderpest, which had destroyed thousands of carabaos, and which had brought agriculture nearly to a standstill, was just beginning to be controlled by vigorous work with protective serums, and cattle were being immunized in China for importation into these Islands. This work had been progressing very satisfactorily, when suddenly, and without warning, hemorrhagic septicemia appeared in a herd of cattle arriving in Manila from Shanghai. At about the same time that the disease was recognized here, reports were received from Hongkong giving accounts of a virulent disease prevalent there, which very much resembled bubonic plague in human beings, and which was called "cattle plague." * Thus far these reports have been so meager that we are unable to state whether or not the disease is endemic at that port, as it seems to be in other parts of the world, and whether or not it corresponds with the disease studied here.

That hemorrhagic septicemia existed in the Philippine Islands previous to the present epidemic cannot be stated with any degree of definiteness. Since our preliminary report† of the present outbreak, some native doctors have stated that they had previously seen animals dying in the same manner as those lately affected, but whether or not these cases were identical with ours cannot be determined. Carabaos are sometimes affected with a condition similar to heat-stroke, and if one of these animals should die in such an attack, the clinical features presented by it might remarkably resemble those of the acute form of hemorrhagic septicemia. One of us had recently seen such a case, in which a carabao, lately landed from a vessel, had been driven through the town and was suffering for lack of water. It suddenly staggered and fell by the roadside, frothing slightly at the mouth, and was unable to rise for at least an hour, and not until it had been drenched frequently with water. If the animal had died in this attack, acute hemorrhagic septicemia might have been suspected, and a correct diagnosis could have been made only after an autopsy. But the foregoing statements of the previous occurrence of hemorrhagic septicemia must be taken *cum grano salis*, for there is a proneness among many physicians and the laity here to recognize any symptom-complex as the disease under discussion at the time. This tendency is well shown by the fact that pseudofarcy is taken for surra by men well acquainted with horses. It is, however, possible that hemorrhagic septicemia has been seen here before, and that the disease has thus far evaded the detection of laboratory men, even though these have a wide experience with cattle diseases.

The disease is a widespread one, and has been noted in almost every quarter of the globe. The first cases were in Germany, and were cited by Bollinger. Later reports of epidemics in Germany have come from Kitt, Jakoby, Buch, and others; from France, Nocard and Leclainche have reported

cases, as have also Galtier and others. Bosso, Oreste, and Armanni, and others have detailed descriptions of epidemics in Italy. Poels reports cases from Holland; Jensen, from Denmark; Piot, from Egypt; Van Eecke, Fischer and Hubenet, from Java; Reischig, Sequens, and V. Ratz, from Hungary; Janson, from Japan; Sanfelice, Loi, and Malato, from Sardinia; Pease, from British India; Carrougeau and Blin and Carré, from Indo-China; Lignières from South America; and Smith, Wilson, and Brimhall, Reynolds, Fennimore, and Nocard, from the United States. It is easy to see how the spread may have included the Philippine Islands, if the disease is a contagious one and not endemic in that archipelago. There is a possibility that China is not to blame for the cases recently discovered here; it may be that the disease is endemic in the Philippine Islands, and that by food or water the organisms gained access to these animals through wounds of the gastrointestinal tract (or even without such wounds), or through wounds on the surface of the body, or possibly by way of the respiratory tract.

It is now settled beyond doubt that organisms resembling those of hemorrhagic septicemia are found in waters and soils. It has also been shown that similar ones are present on the mucous membranes of healthy animals. Moore, of the Department of Animal Industry at Washington, for instance, has demonstrated that organisms resembling those of hemorrhagic septicemia and capable of producing the disease, occurred in 80% of the cattle, 48% of the hogs, 50% of the sheep, 16% of the horses, 30% of the dogs, and 90% of the cats examined by him. Davaine, Pasteur, Gaffky, Gamaleia, S. Mayr and Kitt have found organisms in waters, soils, sputum and bronchial secretions, which, injected into the circulation of animals, caused septicemia which agreed with the usual disease in all its details.

Since this disease so closely resembles bubonic plague, it might be supposed that it corresponds with it also in the sources and means of infection, but these points are awaiting explanation. Since the organisms occur so commonly in healthy animals, it is probable that a lowering of resistance to disease, whether brought about by trauma or by abnormal conditions of environment, relatively increases the virulence of the organisms and brings about conditions from which infection and disease result. This is certainly true in the sporadic pneumonias of cattle, described by Theobald Smith, who believes that the organisms, present in such conditions, are secondary invaders.

The history of the present epidemic of hemorrhagic septicemia in the Philippine Islands is as follows:

A shipment of cattle arrived in Manila Bay from Shanghai on May 28, 1903, and was kept on board until June 1, when the animals were sent to the Perez estate in Paco. On the following day, two of the animals were noticeably ill, and were sent to the Serum Laboratory for observation.

CASE I.—The first animal to die was very weak when first observed, but in fair physical condition otherwise. The conjunctivas were somewhat congested, respiration was rapid and the feces normal. Temperature 30.2° C. When taken off the truck at the laboratory it staggered a few steps and fell on its side. There were numerous bruises on the body, probably the result of a rough voyage across the China Sea. It ate food when placed near it and also drank, although it did not, apparently, suffer from thirst. It had no cough. During the next few days it became a little brighter and somewhat stronger. On June 6 it was again weak and could not stand up, the hind legs seemed to be especially feeble. It gradually became weaker and diarrhea developed, but with no traces of blood or mucus. Death occurred on the ninth day after landing.

The postmortem examination showed a few patches of subcutaneous edema on the sides. There were a few small pericardial hemorrhages about the base of the heart. The lungs showed a number of subpleural nodules, which on section exposed granular areas, similar to those seen in bronchopneumonia in the stages of red and gray hepatization and suppuration. The suppurating areas were filled with a thick, granular, greenish-yellow, sticky material.

Cultures were made from the lung abscesses on agar and blood-serum. After 24 hours at 37° C., the agar tubes showed a growth of small, transparent, grayish, round colonies. The blood-serum showed a very scanty growth of small colonies. Transfers were made from these tubes to various other media, and plates were also made. After a careful study of its morphologic and cultural characteristics, it appeared that the organism under consideration was a short bacillus with rounded ends, and nonmotile. Its measurements varied between 1.0 microns

* Since the foregoing notes were written, the report of the Government Bacteriologist at Hongkong has been received. In this there is a brief summary of the morphologic and cultural characteristics of the organisms found in the animals that died in the epidemic there. This germ grew readily on the "ordinary culture media." It was a bacillus that stained more deeply at the poles, and which did not stain by Gram's method, and which was nonmotile. Its appearance on culture media was similar to that of *B. coli*. All inoculated animals died after 24 to 48 hours, with symptoms of septicemia. From his facts Hunter concludes that he is dealing with a form of hemorrhagic septicemia. But whatever the disease may be, it is not the same one that we are studying, judging from the description of the organism.

† Read at a meeting of the Manila Medical Society, July, 1903

and 2.0 microns in length and 0.3 microns and 0.5 microns in thickness. The largest forms were seen in glucose media, the smallest on potato. From the animal body it showed well-marked polar staining, although this was not so distinct in organisms grown on artificial media. It was stained easily with the usual watery anilin stains, but was not stained by Gram's or Weigert's methods. The rods, as a rule, occurred singly, often in pairs, occasionally in chains of 5 or 6 individuals. The appearance of the growths on the usual culture media was in no way characteristic. The colonies on agar were small, grayish, transparent, and well circumscribed, with little or no tendency to spread. On all the solid media approximately the same appearance was noticed. In gelatin no liquefaction was caused. In bouillon a granular deposit was formed on the sides and bottom of the tube; during the first few hours of growth the whole medium was faintly clouded, but as the sediment was deposited the liquid became clear. After a few days the sediment became viscid, as could be shown by shaking the tube, when the precipitate rose, not in flocules, but in threads. In Dunham's peptone solution the same general characteristics were observed as in broth, but the growth was not so abundant. Indol (cholera-red) was produced rapidly, so that at the end of 24 or 36 hours, the addition of pure sulfuric acid (free from nitrites) produced a wellmarked pink color. No phenol could be appreciated. No gas was produced in solid media containing sugars nor was the reaction changed. Milk remained unaffected, even after 10 days; no acid was produced, no coagulation occurred, and there was no reduction of litmus. Stab

Fig. 1.—Case I.

cultures in solid media showed nothing remarkable. The growth followed the line of inoculation closely, with no tendency to spread, and extended to the bottom of the tube as a finely granular growth, composed of small colonies. The surface growth was small, just surrounding the point of entrance of the needle.

CASE II.—The second carabao was also taken to the serum laboratory on a truck, and on arriving there was unable to walk more than 30 feet. Its eyes were clear, the respiration quickened, and the body covered with numerous bruises. On June 4 it was able to walk and graze, and seemed to be in good condition. On June 14, it was again dull and weak, but still able to walk, the greatest weakness being in the hindquarters. Nevertheless, in spite of a good appetite, and in the absence of other symptoms, the animal gradually became greatly emaciated. On June 21, a swelling was noticed on the inner and outer sides of the left ankle. At this time the animal was hardly able to stand, although the appetite was still fair. The swelling on the ankle was incised by Dr. Slee, and the contents evacuated. The abscess cavity was a loculated one, and the incised tissue was quite edematous. On June 25, diarrhea developed, and 2 days later, when just about to die, the animal was killed and an autopsy done immediately.

The findings were as follows: Beside the incision over the left ankle, there were dried scars on both sides of the body and a small opening discharging a greenish-yellow pus in the left flank over the quarter. Dissection of the left ankle showed that the abscess cavity extended around the joint without involving it, but reaching far up the leg. An opening into the abscess of the flank led into a mass of suppurating glands, which looked much like the broken-down ones of bubonic plague, save that the contents were more granular. The tissues about these suppurating areas were infiltrated, with a gelatinous exudate of a distinct yellow color. In the intermuscular and surrounding tissues there were more or less wellmarked hemorrhages. On skinning the animal, a widespread subcutaneous gelatinous edema was discovered, with large and small hemorrhages. In the stomach walls and beneath the pericardium and the pleura, hemorrhages were present, some of which were well circumscribed and others irregular in outline. There was a very large

extravasation of blood into the mediastinal portion of the parietal pleura, and another similar one along the descending aorta.

The lymph-glands were generally enlarged, pale and edematous, but some were smaller and hemorrhagic. There were petechias in some of the edematous glands. The lungs were, for the most part, crepitant, although there were areas in the left one which resembled the stage of red hepatization of bronchopneumonia. The spleen was of about normal size, with no hemorrhages into its substance, but with many subcapsular ones. The liver showed nothing remarkable. The kidneys were of fair size and the perirenal tissues were edematous; their pelvises were filled with a gelatinous material. There were no hemorrhages into mesentery.

In the abscesses from the left ankle and from the hind quarters small polar-staining bacilli were found in almost pure culture. Smears from the lymph-glands showed similar organisms, but the heart's blood was apparently free from them.

Cultures showed an organism that corresponded with that from Case I.

CASE III.—This animal, a full grown carabao, was apparently perfectly well until one morning, when it looked stupid, its gait was clumsier than usual, and its eyes appeared to be sunken. It did not care to use the mud-bath but wandered about aimlessly. (The native overseer said that it was insane). On the third day weakness across the loins and in the forelegs was evident. Its appetite was still fair. On the morning of the fourth day it fell over and was unable to rise again, and died in the afternoon.

Smears showed a few organisms that were polar-staining. Culture on placenta fluid showed organisms that resembled diplococci. Culture lost in moving.

CASE IV.—This animal was stupid and weak when first noticed and as nearly as could be determined had been sick for about 3 hours. It kept on its feet and moved from place to place for several hours, eating occasionally. Death took place suddenly.

Smears from organs showed a few polar-staining organisms. Cultures not made.

CASE V.—This carabao lived about 3 days after the appearance of the first symptoms, the principal one of which was weakness, especially in the forelegs. At autopsy the base of the heart was edematous and there were scattered areas of subcutaneous edema with a few hemorrhages.

CASE VI.—Death was very sudden, occurring 24 hours after the beginning of the illness. Autopsy revealed edema and bloodstained infiltrations about the inguinal and prescapular glands. The latter were much swollen and showed areas of necrosis and a few small hemorrhages in their substance. Hemorrhages, varying in size, were present in the inner and outer surfaces of the intestines, under the visceral and parietal pleura, under the parietal and visceral pericardium and under the endocardium. Petechias were present on the surface of the liver and were especially well marked on the inner surfaces of the branches of the portal vein. A few small hemorrhages were found under the capsule of the spleen and under the surface of the diaphragm.

Smears from lymph-glands, liver, spleen and lungs showed polar-staining bacilli.

CASE VII.—The duration of the illness was 2½ days, during which the animal could scarcely stand, although the appetite remained good. The almost characteristic edemas were well marked in this case and polar-staining bacilli were found in smears.

CASE VIII.—This animal, one of the finest in the herd, was alive and well on the morning of June 7; the following morning it was found dead. The postmortem examination showed hemorrhagic edema under the skin along the spine, about the prescapular glands and around the base of the heart. There were ecchymoses on the surface of the heart, under the capsule of the spleen, in the inguinal and prescapular glands, in the pancreas, in the gallbladder, and under the serous and mucous surfaces of the intestines.

Smears from heart and spleen showed polar-staining bacilli, some of which showed evidences of having been a capsule or pseudocapsule. In this case blood-serum had no agglutinative reaction on the bacilli previously obtained from other cases.

CASES IX and X were calves. The clinical histories and the details of the autopsies are wanting. All that is known is that in neither case was the spleen enlarged, that there were subcutaneous gelatinous edemas, and that the usual edema was about the base of the heart in each.

CASE XI.—In this case also, the clinical history is wanting, but the same pathologic changes that were observed in the two previous cases were present. Smears from the blood showed a number of polar-staining bacilli occurring singly or in chains of 3 or 4 individuals. Cultures were made from the heart's blood on agar and an organism was obtained in pure culture, which corresponded to that isolated from Case I.

CASE XII.—This animal died within 24 hours after the appearance of the first symptoms. It was large and well nourished, and when examined was lying on the ground, the legs stiff and the head drawn back. The agonal stool was bloody. There were hemorrhages along the spine into the subcutaneous tissues, as well as on the surfaces (inner and outer) of the small intestine. The prescapular glands showed areas of hemorrhage and necrosis.

CASE XIII.—This was a fairly well-nourished carabao, which had arrived from Shanghai 3 days previous to the appearance of illness. It was well on the evening of July 22. On the following morning it was found dead. In this case the lesions were confined to the heart and lungs; the subcutaneous gelatinous edema seen in the other cases was absent. The lungs were not collapsed and contained air in only a few patches. The costal pleura was intensely inflamed and showed numerous ecchymoses and was covered with a thick stratum of fibrinopurulent exudate. The visceral pleura was in a similar condition. The mediastinum was filled with a mass of yellow gelatinous material composed of serum and fibrin. On section the lung tissue was red, in places very dark, and divided into large and small lobules by white fibrous and fibrinous bands intersecting in all directions. These bands varied from an eighth to a half-inch in width and were studded with loculi, containing a serofibrinous and fibrinopurulent material. In the pericardial cavity was a large amount of serous fluid, containing

Carabao No 68 (w/ltg 217) II
 June 7 1903
 Weight 900 Age 15 Sex (Male) Color (Black) Inoculation Rinderpest
 History from Shanghai

Fig. 2.—Case II.

floccules; both layers of the pericardium were covered with fibrinous shreds. The serous membrane under this exudate was inflamed and dotted with ecchymoses. The auricular appendages were thickly mottled with hemorrhages.

Smears from the heart's blood, lungs, liver, and lymph-glands showed a considerable number of polar-staining bacilli, and cultures showed a similar organism in uncontaminated growths.

This case followed closely the description of sporadic pneumonia as given by Theobald Smith.

Beside the cases of hemorrhagic septicemia seen in carabaos, a native horse was found to be suffering from a malady which was caused by the same organism. In this case the chief lesions were found in the lungs, and these corresponded perfectly with those of Case I. There was also a wellmarked gelatinous edema about the base of the heart. The organism was recognized in smears and cultures and identified with that from Case I.

In summarizing the chief clinical features of these cases, we can say that there have been 3 fairly well-differentiated types: One, intensely acute, in which the animals died within a few hours after the onset of symptoms; one less acute, in which the animals suffered chiefly from weakness in the limbs, and more especially in the hind ones; during the course of this form of the disease the appetite was little or not at all affected; lastly, one in which the course was prolonged, accompanied by great weakness and emaciation, and occasionally by suppuration. These are not distinctly defined types, for rarely does the disease affect the animals in the same way, except in the acute form, in which the course is so rapid that there is little time to observe symptoms.

The pathologic types are as indefinitely defined as the clinical types. In a general way, however, there is a pulmonary type in which the lesions resemble those of bronchopneumonia, sometimes with abscess formation, and with or without pleuritis. Combined with these changes there may be marked changes in the interlobular tissues, with the formation of fibrous bands, and with emphysema. Another type is the rapidly fatal septicemic form, in which there are few macroscopic changes in the organs beyond incipient parenchymatous

degenerations. The third type is a glandular and suppurative one, which terminates in a general infection. In all these forms there have been more or less widespread hemorrhagic lesions, combined with gelatinous edemas. This last named condition was especially frequent about the base of the heart, and in some cases it was the only macroscopic lesion.

In but few cases have complete temperature charts been kept—this because most of the animals have come from herds regarded as healthy, and have died too suddenly to allow records to be prepared. The temperature charts of Cases I and II will, however, be appended. These curves show very little except a primary rise of temperature, after which there is a fall, with the subsequent curve running either near the base line or very irregularly.

The clinical cases given above agree in many points with those described in the literature, but in many details, too, they do not. Wide variation clinically and pathologically seems to be one of the most common features of the disease caused by *B. plurisepticus*.

In Bollinger's report the cases are divided into an exanthematous and pectoral type. The former is characterized by fever, swellings of the face and neck, inflammation of the mouth and tongue, with ecchymoses under the mucous membranes, and bloody diarrhea. Such cases we have not seen, nor have we observed any cases resembling them. This may be because the hide of the animal that we meet here is thick enough to prevent the edematous swellings from becoming apparent, for certainly in the majority of cases there have been subcutaneous edemas, some of quite considerable size. The latter type showed, principally, pulmonic lesions. We have studied 3 cases that followed this type, 2 in carabaos, and 1 in a horse. In 1 carabao, and in the horse, the chief lesion was a bronchopneumonia without pleuritis; in the other carabao it was a pleuropneumonia.

Lignières divides the cases he has seen into 3 classes: First, a diarrhetic one—the acute form—in which death occurs in from 1 to 2 days after the onset of the diarrhea. In this, pectoral lesions are common (*i. e.*, pneumonia, pleurisy, etc.) The second class he calls *Éntéque*. The course of this form is more chronic, and the animal may live for 3 to 4 weeks with more or less fever and fetid diarrhea, culminating in anemia and death. The third or cachectic form is marked by wasting, articular localizations and profound anemia, followed by death.

Speaking generally, the commonest types in the literature are the exanthematous and pulmonary. Oreste and Armanni described cases in which edemas and hemorrhages were the chief lesions; many of Kitt's animals showed pneumonia and pleuritis; Jensen's showed phlegmonous edemas, fibrinous pleuritis and pericarditis, and gastroenteritis; Galtier described hepatization of the lungs, subendocardial hemorrhages and peritonitis; Guillebeau and Hess found fibrinous pleuritis and pericarditis, hemorrhagic infarcts in the lungs, and small hemorrhages into the mesentery and on the surface of the kidney; Bosso described hemorrhages into the serous membranes and into the mucous lining of the intestine; Pease observed cases in which the chief lesions were ecchymoses, widely disseminated in the bodies; Fennimore remarked inflammation of the mucous membranes of stomach and intestines, pleuritis, pericarditis, and edema of the lungs; and Smith carefully studied and minutely described peculiar lung lesions in which interlobular changes were an important feature.

From a summary of the facts given in the literature, we may conclude that the animals attacked are of all ages, the onset is usually sudden, the course is rapid, and death occurs in from 85% to 98% of the cases. In the less rapid forms of the disease the symptoms may be refusal of food, cessation of rumination and lactation. The initial rise of temperature may be followed by a drop to normal or subnormal. The respirations may be rapid or labored; bloody material may be discharged from the nostrils, bowels, or bladder, and noncrepitant swellings may occur on face, neck, or about the back and ankles.

From all these varying types of disease similar organisms have been isolated. In the outbreak which we have studied the characters of the microbe have been as follows: Short bacilli with rounded ends, polar-staining, occasionally encapsulated and nonmotile; nonliquefying, non-Gram staining, grow-

ing invisibly on potato, not producing gas, not coagulating milk or reducing litmus, producing indol and nitrites and not forming spores. It is an organism which corresponds closely with the bacilli of hemorrhagic septicemia of Hueppe, and especially with that member of the group called *B. bovissepticus* (Kruse), *B. bovissepticum* (Kruse-Migula), *B. plurissepticus* (Kitt), *B. bipolare multocidum* (Kitt), *B. der buffelseuche* (Oreste-Armanni), etc. The chief differences between the present bacillus and the ones described in the literature are its indol production, which is invariable, and its invisible growth on potato, which also appears constant.

Animal Experiments.*—The organism has been injected into guineapigs, rabbits, monkeys, small birds, a dog, a chicken, and a calf. In all but the last 3 animals death has followed in from 9 to 24 hours after intrapleural injection, in 5 to 18 hours after intraperitoneal inoculation, and in 5 to 14 hours after intravenous injection of virulent material. Subcutaneous injection with a culture kept at 60° C. for 10 minutes killed a rabbit in 36 hours. Intravenous injection with the same material killed in 18 hours. In both these last two cases the organism was recovered from the heart's blood.

The lesions in animals killed with virulent cultures varied with the length of the disease and with the animal used. In all, there were edema and some hemorrhagic infiltration or ecchymosis at the site of inoculation. In addition to this, 2 or 3 cases were noticed in which there were large collections of pus surrounded by tissues in a state of coagulation-necrosis in the immediate neighborhood of the wound of inoculation. The more resistant the animal and the more attenuated the organism (within certain limits), the greater was the tendency to suppuration.

The protocols of the animal cases are as follows:

RABBIT 321.—Inoculated subcutaneously with 0.5 cc. of an emulsion of a 24-hour old agar growth. (Organism from Case I.) Dead in 18 hours. Large hemorrhage at site of inoculation, and a few small ones in axillary and inguinal glands. Lungs congested, vessels of the heart distended with blood. Liver soft, and showed diffused pale areas of fatty or necrotic tissue. Adrenals congested. No changes in gastrointestinal tract. Small amount of fluid in peritoneal cavity.

Smears from the liver, spleen, heart's blood, and site of inoculation showed the typical organisms, which were recovered in pure culture from the blood.

RABBIT 322.—Inoculated subcutaneously with 1 cc. of a suspension of a 24-hour old agar growth of the organism obtained from Case XIII. Dead in 5 hours. No wellmarked lesions. Some edema about the wound of entrance. Liver and kidneys congested. No hemorrhages or necroses. Smears from heart's blood, spleen, kidney, and liver showed the typical organisms, and these were obtained in pure culture from the blood.

RABBIT 335.—Inoculated intravenously with 1 cc. of a bouillon culture of the organism from Case I, which had been kept at 58° C. for 10 minutes. Dead 24 hours later. Autopsy showed focal necroses in the lower lobes of both lungs, in liver and spleen. Smears from spleen, kidney and blood showed a few small polar-stained bacilli, which, however, were recovered in pure culture.

MONKEY 256.—On June 16, 1 cc. of a bouillon culture was injected under the skin of the right side. On June 18, 1 cc. of a culture in placenta fluid was injected into the peritoneal cavity. Death occurred 6 hours after the second inoculation. About the points of inoculation were areas of edema. Surrounding the point of inoculation on the right side was also a large intermuscular abscess filled with a pale, greenish-yellow, gelatinous pus. Practically the whole right side of the animal was the seat of a subcutaneous gelatinous edema. The peritoneal cavity contained a large amount of sanguineous fluid, and the luster of the peritoneum was dulled, and it was injected. The other lesions were cloudy swellings of the parenchymatous organs.

Smears from the spleen, liver, and peritoneum, and from the pus at site of inoculation showed polar-stained organisms. None seen in the blood. In several leukocytes from the peritoneal cavity polar-stained bacilli were seen. The heart, peritoneum, and liver showed pure cultures of this organism.

MONKEY 297.—Inoculated intraperitoneally with 1 cc. of a broth culture of the organism from the horse mentioned above. Death in 36 hours. The abdominal wall about the wound made by the needle was edematous. The scrotum was distended and edematous. There were wellmarked subcutaneous ecchymoses and gelatinous edema with a certain amount of purulent infiltration. Coils of intestines were adherent, and there was a quantity of sanguinopurulent exudate in the peritoneal cavity. The pus extended down along the spermatic cords into the scrotum. The left testicle was much enlarged and contained some purulent and ecchymotic areas. The right testicle was small, and surrounded by a purulent exudate. The intestines showed

a few small hemorrhages under the serous layer. The other organs showed no marked change. Smears from the abdominal cavity, liver, spleen, subcutaneous abscess, and testicular abscesses showed polar-stained bacilli. These were recovered in pure culture.

These case reports of animals dying spontaneously and those dying after inoculation will give some idea of the ability of the organisms to cause widely varying types of disease. It is as Reynolds has said: "For the present at least, we must consider the term, hemorrhagic septicemia as quite inclusive, a sort of generic name, which must cover a multitude of varying types of disease."

When we encountered the first cases of the present epidemic we feared that the outbreak might take on as dangerous proportions as it had in some of the epizootics first reported, and as time has gone on this fear has been partially realized, but we still hold to the idea that the cases have been the direct result of trauma in many of these and the indirect result of infection with an organism present in the mouths of healthy animals.

It does seem very probable now that a pasture may become infected, and that new animals placed on such infected ground may die of the disease in one of its forms, especially if the animal is in any way predisposed to disease. For this reason it seems most unwise, in the present state of our knowledge of the disease, to move animals from place to place, and so risk infecting new ground to be used by well animals.

In one of the corrals in Manila, a few animals in one herd had died. Following these deaths came heavy rains, so that the corral became a great mud-hole. Into this place a new herd of carabaos was driven after they had crossed the China Sea from Shanghai. Following the advent of these animals deaths occurred rapidly, and in all but a few of the dead, the lesions of hemorrhagic septicemia were found.

It is our opinion that the disease was the result of the rough sea voyage, change of diet, the preliminary inoculation against rinderpest, and finally the filthy surroundings in Manila. Under these circumstances disease might be expected.

The question concerning the source of the infection by which death resulted remains to be answered. Were the organisms in the animals themselves? Were they in the mud of the corral? Neither of these questions can be answered positively as yet. We have not been able to find the bacilli in the mud. But just so long as there is any doubt, the animals must be treated as though they could scatter the germs of the disease with their excreta.

Up to the present time there has been no evidence that the disease here is directly contagious, but Carrougeau and Blin, Bollinger, Friedberger and Frohner, and others, considered the disease which they studied was. On the other hand, Nocard and Leclainche think that the cases are sporadic and that the disease is enzootic, and Wilson and Brimhall and Reynolds believe that it is not contagious.

For the purpose of eliminating all, or most chances, of contagion we suggest that each animal in a suspected herd should be isolated or staked out separate from the rest of the herd for at least 10 days after the occurrence of the last case in the herd to which it belongs, and until any abrasions on the surface of the body have healed. (Brimhall and Wilson have suggested that skin lesions may play a part in the spread of the disease.) While the herd is under suspicion none of the animals should be allowed to use the mud baths. After an animal has died, the ground upon which it has stood should be cleansed by fire or antiseptics, and if it has had access to the mud bath this should be disinfected in the most thorough way with lime or crude carbolic acid and then flushed out with water. There seems to be some difference of opinion as to whether the organism is able to live any length of time in contaminated water, but since similar ones have been found in rivers and in soil, it is wiser to be on the safe side and use all precautions. Theobald Smith states that the organism is very vulnerable and Nocard and Leclainche say that it is a facultative parasite. The result is, that for the present, it must be dealt with as though its resistance were great. Kitt, in Kolle and Wassermann's Handbuch, recommends that it be treated as though it were the bacillus of anthrax.

Up to the present time we have been unsuccessful in obtain-

*In these experiments, Mr. Clegg, Assistant Bacteriologist in the Biologic Laboratory, has given us much valuable assistance.

ing any serum or protective substance that will modify or ameliorate the course of the disease in experimental animals. Work along these lines is, however, being done and will be made the subject of a later report. Wilson and Brimhall report that they were able to produce a fairly high degree of immunity. In the book on "Les Maladies Microniennes des Animaux" by Nocard et Leclainche, it is stated, that the belief of Lignières, that the organism of bovine pasteurellosis can be attenuated and used as a vaccine, is possible. The details of his method are not given and thus far we have been unable to obtain them.

Note.—We have been interested to hear, since the notes for this report have been prepared, that there have been epidemics of an unknown nature among chickens and swine in the provinces about Manila. The reports make it seem probable that these diseases are related to the hemorrhagic septicemias of fowls and hogs. We have received from a gentleman in Manila a chicken that had died suddenly. From this we have isolated an organism that resembles the bacillus of chicken cholera, which, when inoculated into small birds in minimal quantities, gives rise to a rapidly fatal septicemia that corresponds exactly with the disease chicken cholera. In inoculating with this organism a needle, the tip of which was covered with a culture of the organism, was plunged through the skin and into the subjacent muscles. The disease prevalent among swine remains to be determined.

These observations make it seem probable that chicken cholera is endemic here, and, if there is any value in analogy, that other forms of hemorrhagic septicemia may be.

9. The Red Cross Society of Japan. N. SENN.

1.—Early Signs of Pregnancy.—H. L. E. Johnson describes a sign existing prior to and including the third month, invariably noted and after whose appearance pregnancy has been demonstrated. It can be seen by the fourth week and possibly earlier and consists of an intermittent softening and hardening of the vaginal portion of the cervix, with, in many cases, a change of color from a pale violet to the normal pink hue or the reverse. These changes in color and consistence are rhythmic more or less and are probably early manifestations of intermittent contractions of the pregnant uterus, due probably to a necessity for some change or modification in the uterine circulation incident to the nourishment and growth of the ovum. The writer has never observed this sign in any other normal or diseased condition. He reports a number of cases diagnosed when pregnancy was unsuspected by the patient. [H.M.]

3.—See *American Medicine*, Vol. V, No. 23, p. 985.

4.—See *American Medicine*, Vol. V, No. 20, p. 784.

5.—Hard Tissue in the Pulp.—D. E. Caush divides the development of secondary dentin into normal, dentin of repair, pulp nodules, and that found where pyorrhea alveolaris has been pronounced. It is sometimes found apparently without any cause, when, as a rule, no inconvenience is produced by its development, and it is detected only after extraction. The cause may be slight irritation from constant use of the teeth. He describes the process of calcification. The dentin of repair is found with erosions and decay, and in teeth worn down by attrition and mastication. The pulp nodule is due to irritation in the pulp itself. Immediately under an eroded surface the tubules stain with difficulty, if at all. It appears as if they had been filled with some deposit from the outer surface that prevents them from performing their usual functions. The secondary dentin is to prevent acute irritation passing from the eroded surface to the pulp itself. In the writer's experience secondary dentin is found with decay only when the latter has been slow and the irritation of the pulp slight and continuous. The earlier tissue contains, as a rule no tubules, but lacunas with canaliculi. The deposits due to attrition and mastication are quite structureless at the commencement, passing from that through other forms to a dense mass filling the pulp chamber. The pulp nodules may produce much pain if so situated that they press on nerves. It grows usually by concentric rings. Its mode of development is similar to that of the pearl, the exciting cause being perhaps some dead cells or escaped blood-corpuscles. [H.M.]

6.—Splenic Anemia.—M. J. Lichty reports a case in full, adding a review of the literature of the subject and giving the main symptoms and treatment. Of 34 cases collected, 26 were males, 8 females; average age, 36. Malaria was found in 7, syphilis in 2. Melanoderma was present in 17 cases. Splenic enlargement was the most prominent feature in all, and anemia the next. Hemorrhage occurred in 24. Hemoglobin averaged 47%, the red cells 3,293,000, white cells 5,594. Excluding 2 cases in which there was leukocytosis, the leukocytes averaged 4,381. The liver was enlarged in 16 cases, small in one. Ascites was present in 7, swelling of feet and legs in 9, glandular enlargement in 3, gastrointestinal symptoms in 8, and cardiac murmurs, generally hemic, in 11. In only 2 cases was there albumin, a trace, while the one reported by Lichty had consid-

erable at times, as well as pus and casts. Of 25 cases treated medically, only 5 recovered, 12 were improved, and 7 died, hemorrhage having been the commonest cause. Operation was performed on 8 cases, of whom 5 recovered and 3 died. [H.M.]

7.—**Squint.**—A. B. Hale thinks this subject should be annually discussed at mothers' meetings as it is through the mother it is to be detected. In the young adult operation does not always lead even to cosmetic improvement and in the majority of cases the eye is after all a useless organ. The time to treat it is as soon as it is noticed. Neither nerves nor muscles are primarily at fault, but the brain, where the fusion function is located. Treatment consists in correction of refractive errors, training of the fusion sense, operation. The first is the essential factor, the second of great importance and implies such methods as the occlusion bandage, atropin to the good eye, stereoscopic, amblyoscopic, and other visual exercises. Operation is usually necessary, though squint may be entirely overcome without it. The writer's preference is for advancement. [H.M.]

1. Remarks upon Cholecystectomy and Cholecystostomy, with Special Reference to their Comparative Safety and Efficiency in the Treatment of Biliary Affections. MAURICE H. RICHARDSON.
2. Cholecystostomy and Cholecystectomy: A Study of a Certain Series of Operations. CHARLES L. SCUDDER.

1.—**A Comparison of Cholecystectomy and Cholecystostomy.**—Maurice H. Richardson bases his opinions upon some 200 cases operated upon by himself, together with observation in several hundred additional cases seen in hospital wards. He says the practical arguments in deciding between extirpation and draining the gallbladder are 3 in number, namely: (1) Upon the comparative danger of the 2 methods; (2) upon the comparative efficiency of preventing the recurrence of stones; (3) upon the advantages of temporary drainage of the biliary passages, and upon the possible necessity and increased difficulty of draining these passages at some future time. In discussing these several points, he states that clinical experience shows cholecystotomy to be the safest of all operations upon the biliary passages, though there are conditions in which drainage is quite as dangerous as extirpation, such as when the gallbladder is deeply contracted, hard to find, and adherent to the surrounding viscera and infected. He believes that gallstones are rarely reformed even in the gallbladder, though the argument of liability of reformation favors cholecystectomy rather than cholecystotomy, but the weight of this argument is very light. In regard to drainage of the biliary passages, he says: It may be affected after extirpation of the gallbladder by means of the cystic, common, or hepatic ducts, but this operation is not so easy or so safe as is regarded by some. Therefore, when it is proposed to extirpate such a gallbladder it is proposed to do away with drainage, except by methods difficult and dangerous. The most important objection to extirpation is the loss of the great benefits which follow prolonged drainage of the biliary passages, and it is a serious objection to extirpation that drainage in the future will be difficult. In some instances of highly contracted and adherent gallbladder, cholecystectomy is a necessity, but when cholecystotomy can be performed the author appears to favor that method, though he confesses that during the past year he has performed more cholecystectomies than heretofore. He holds that while there is a certain analogy between the appendix and the gallbladder, it is not so great as is apparent at first thought, and that the latter is simplicity itself when compared to the former. The anatomy of the biliary passages is complex, the ramification of the bile ducts far reaching, and the anatomic relations are of the first magnitude. [A.B.C.]

2.—**Cholecystostomy and Cholecystectomy.**—Charles L. Scudder reports a series of 16 patients operated upon for gallstones. In 7 instances cholecystostomy was performed and the gallbladder attached to the abdominal parietes by suture to the peritoneum, drainage being thus established. There was 1 death. Five of these cases have been followed carefully; only 1 is absolutely well and in each of the other 4 there is more

or less discomfort. The facts in each case are given in detail. In 9 instances cholecystectomy was performed. All recovered and all the patients have been traced, a report being obtained in each instance. The longest time which has elapsed since the operation is 3 years, and the shortest, a month. In no instance has there been a recurrence of gallstone colic and each patient considers herself well. Of the 16 patients 11 or 68% showed no jaundice. He cites a series of 24 cases reported by Winslow in which cholecystectomy was performed, 2 patients died, and in the remaining 22 the recovery was complete, there being no recurrence of pain or discomfort. He likewise quotes Winslow as stating that of 183 patients operated upon for gallstone in the Massachusetts General Hospital within the last 10 years 29 or 18% came to secondary operation, most of them because of biliary fistulas following cholecystostomy. His conclusions are that cholecystostomy should be done in those cases of gallbladder and biliary duct surgery in which quick drainage is needed for the deeper ducts and in which the surgeon is not absolutely sure that the deeper ducts are entirely free. Cholecystectomy should be done in cases of acute cholecystitis, in cases of cholecystitis resulting in gangrene and empyema of the gallbladder, in small contracted (infected) gallbladders which are functionally useless and which will not be of service in facilitating drainage, and in all cases in which the surgeon is morally sure that the deeper ducts are free from obstruction. [A.B.C.]

Medical Record.

February 20, 1904. [Vol. 65, No. 8.]

1. Heart Syphilis. I. ADLER.
2. High-frequency Currents in the Treatment of Skin Diseases. CHARLES W. ALLEN.
3. The Medical Aspect of Accidents Caused by the Röntgen Rays. CARL BECK.
4. Insomnia. ELIOT GORTON.
5. Common Duct Stone Associated with Acute Septic Cholangitis. GEORGE EMERSON BREWER.
6. A Case of Choroidal Inflammation, with Permanent Loss of Vision, Caused by Excessive Use of the Eyes During a Comparatively Short Period of Time. D. B. ST. JOHN ROOSA.

1.—**Cardiac Syphilis.**—I. Adler reviews the literature of the subject and says: Cardiac syphilis is not a rare, but rather a common disease. It is often possible to make a diagnosis of heart syphilis with certainty; more frequently the diagnosis is one of probability. In conclusion, he says that syphilis as a possible factor should be considered in every case of heart disease, so on the other hand, a possible heart disease should be considered in every case of syphilis. Most syphilitic heart lesions remain latent for a long time without giving rise to any subjective symptoms, or these latter are so very slight as easily to escape the attention of the patient as well as of the physician. Often very serious cardiac disturbance, apparently quite acute and without premonition, or a surprisingly sudden and entirely unexpected death of heart failure, testifies to the fact that pathologic changes must have been going on in such hearts for a long time unnoticed. It must be borne in mind that the pathologic changes must be considerably advanced before they cause subjective or clinical symptoms. [A.B.C.]

2.—**High-frequency Currents in the Treatment of Skin Diseases.**—Charles W. Allen gives a practical review of the subject, and answers the questions: 1. What are high-frequency currents? 2. How are they produced? 3. How are they applied? 4. How is their action accomplished? 5. Of what value are they in dermatotherapy? He bases his observations on 175 histories in which record has been made of these currents. The cases recorded include 37 of acne, 26 of alopecia, 27 of eczema, 8 of pruritus ani, 8 of pruritus vulvæ, 2 of generalized pruritus, 5 of pityriasis rosea, 3 of urticaria, 4 of lichen planus, 1 of mycosis fungoides, 3 of zoster, 3 of rosacea, 2 of pruritus hiemalis, 1 of pruritus seroti, and scattered cases of psoriasis, chloasma, ichthyosis, keratosis, pilaris et follicularis, warty growths, moles, erythema nodosum, generalized molluscum contagiosum, scabies, dermatitis, dermatalgia, ulcers, etc. In conclusion he states that high-frequency currents are of decided advantage to those treating skin diseases, but are especially to be employed in connection with other measures. They are curative of themselves in a restricted class of cases. [A.B.C.]

3.—Medicolegal Aspects of Accidents Caused by the Röntgen Rays.—Carl Beck cites a number of instances in which suit has been instituted for accidents and burns resulting from röntgen ray treatment, and points to the diversified character of opinions rendered by court and juries. He says: In severer cases it appears to be natural that the patient is only too much inclined to blame his examiner. Whether the operator was negligent or not seems to be immaterial to the great majority of the injured; all they see are the consequences. Although with our present means it should not appear difficult to settle the question whether the physician has committed negligence or whether he or his patient is the victim of unfortunate circumstances, there is hardly any subject in the field of medical jurisprudence where juries, judges, and experts disagree as much as in this field. The decisions of the courts in this country, as well as in Germany, England, France, and the Netherlands illustrate a deplorable state of affairs. French courts excelled in decisions against physicians, especially in all cases in which the corpus delicti has consisted in injury to the complexions of the fair sex. [A.B.C.]

4.—Insomnia.—E. Gorton thinks too much reliance is placed on drug treatment. In sleep there is contraction of the cerebral vessels and dilation of the peripheral vessels throughout the body. There are various hydrotherapeutic measures which will bring this about, but results depend on a careful technic. In many cases the various methods of treatment should be combined. The warm, full bath before retiring, followed by a hot drink and a hypnotic in moderate dose, is of great value. The head during the bath should be enveloped in a towel wrung out of cold water. The duration of the bath should be from 15 to 25 minutes and the water should be kept at 98°. The patient should not be rubbed in drying, as this has an exciting effect. The cold, wet pack is equally efficacious, accompanied by cold to the head and face. The sheet should be wrung out of water at 70°. Warm sitz baths 95°, 20 minutes to an hour in duration, exert a distinctly sedative effect. This bath may also be used at 50° to 68°, 2 to 5 minutes, with the same effect, when there is no inflammation. The foot bath at either 104° or 54° is beneficial, the bathing being kept up until the feet are intensely red. Paraldehyd is one of the best and safest hypnotics in 2 dram doses, repeated if necessary. An irritable stomach contraindicates its use. Trional is fairly free from unpleasant after-effect. Sulfonal is often depressing. Bromid should be followed the next day by the half bath, this controlling the acne. A smaller dose is effective if all salt is withdrawn from the food. The insomnia of physical fatigue can sometimes be overcome by a mild stimulant, such as strychnin or ale. A half bath or cold dip often acts like magic. Under no circumstances should a patient be allowed to continue his accustomed work into the evening hours. [H.M.]

5.—Common Duct Stone Associated with Acute Spastic Cholangitis.—George E. Brewer reports 3 cases, at length, and discusses the subject intelligently. He states that it is not well recognized that a certain number of these cases present in addition chills, fever, and sweating, so characteristically intermittent in character as strongly to suggest a malarial infection. The condition is one of gravity, and unless promptly relieved by surgical means, leads, almost invariably, to a fatal termination. The only treatment that can hold out any hope of success is surgical, choledochotomy, removal of the stones, and hepatic drainage. In the first 2 cases which he reports, the acute symptoms had existed for several weeks, and the progress of the septic intoxication was gradual; while in another case the symptoms were grave and alarming from the first, and the progress of the sepsis was rapid. These patients, if unrelieved, suffer greatly, and eventually die from a combination of exhaustion, sepsis and cholemia. In the severe type of the disease, the patients die promptly, unless relieved at a very early period, and the autopsies show a septic and often virulent cholangitis, edema of the liver and innumerable small abscesses. [A.B.C.]

6.—Loss of Vision from Excessive Use of the Eyes.—D. B. St. J. Roosa reports the case of a physician who brought on an attack of choroiditis with a central blur by reading almost continuously through 10 hours a book with rather small type. Such a result is seldom seen by the oculist as the asthen-

opia induced usually causes the patient to desist before the danger line has been crossed. With our advanced knowledge in infectious diseases we sometimes are inclined to ignore primary mechanical and chemic causes. [H.M.]

New York Medical Journal.

February 13, 1904. [Vol. LXXIX, No. 7.]

1. The Conservative Treatment of Some Surgical Diseases of the Renal Pelvis and the Ureter by the Uterocystoscope. F. KREISSL.
2. Personal Experiences with the Administration of Nitrous Oxid and Oxygen for Prolonged Anesthesia. PRESCOTT LE BRETON.
3. Original Research Regarding Human Perspiration. JULIUS H. HOELSCHER.
4. Artificial Fluorescence of Living Tissue in Relation to Disease. WILLIAM JAMES MORTON.
5. Fluorescein in Transillumination of the Stomach. ROBERT COLEMAN KEMP.
6. Truncæck's Serum. SWITHIN CHANDLER.

1.—The Uterocystoscope in Renal Diseases.—F. Kreissl believes that the efficiency of the cystoscope as a therapeutic means has been grossly exaggerated, but he believes that when it is judiciously employed, it has its useful but very limited sphere. The method has many limitations caused by various abnormal conditions along the route the catheter or bougie has to traverse. The conditions which might call for the employment of this method are: Hydronephrosis, pyelitis, pyonephrosis, ureteritis, pyelonephritis, renal retention, and colic obstructions of the ureteral lumen by calculi, clots of blood or pus, strictures or displacements of the ureter, with their results, encroachment on the ureter by various pathologic conditions from without. He says that in several of these conditions temporary relief can be obtained by the endoureteral intervention, and in a very small fraction permanent results will be observed. [C.A.O.]

2.—Nitrous Oxid and Oxygen in Prolonged Anesthesia.—P. Le Breton clearly sets forth the advantages and disadvantages in the use of this anesthetic, and in conclusion says that its use for prolonged anesthesia is satisfactory, but limited. The wealthy class alone can demand it, because of the cost of materials and the larger fee for the engagement of an experienced anesthetist. The bulky and expensive apparatus, and the difficult method of administration are not inviting, and the occasional lack of smoothness in the narcosis discomfits the surgeon. Hence the employment of this method will be reserved for anesthetists in the larger cities, in the case of operations upon the extremities or trunk, where the condition of the patient demands an anesthesia free from danger and practically free from after-effects. The deservedly increasing popularity of the gas and ether combination predicts a similar popularity of the use of gas, oxygen and ether, when the gases are used until the incision is made and after the suturing is begun, and the ether provides complete relaxation and freedom from cyanosis during the operation proper. The contraindications are chronic alcoholism and wellmarked arteriosclerosis or cardiac lesions. [C.A.O.]

3.—Human Perspiration.—The paper by J. H. Hoelscher deals with analyses of human sweat in normal and abnormal subjects. The following arrangement is submitted: Twenty-five passive, normal sweats; 22 passive, normal sodium salicylate sweats; 25 passive, normal pilocarpin sweats; 10 passive, normal acetanilid sweats; 7 passive, normal quinin sweats, and miscellaneous sweats. The chemic analysis is limited to the determination of reaction, specific gravity, total solids, organic and inorganic, urea, and nitrogen; also uric acid, sugar, bile, etc., to a few specimens. The pilocarpin sweats, with a few exceptions, contained more organic than inorganic solids; the quinin sweats exceeded in inorganic solids; the salicylate sweats were about evenly divided, relative to organic and inorganic solids; the passive sweats slightly favored the inorganic solids; and the acetanilid sweats favored the organic solids. Among the clinical features it is important to note that the induction of passive hot air sweats, coincident with the administration of the drugs mentioned, lessens the toxic effects of the drugs. From the experiments cited the following deductions are made: 1. The hot air bath causes an aseptic fever, or temperature elevation, despite the antipyretic action of acetanilid, sodium salicylate, and quinin sulfate. 2. The hot air bath is of decided value in acute and chronic uremia. This is shown by

the fact that the perspiration contains a considerable excess of urea and nitrogen. 3. In articular rheumatism in conjunction with the salicylates, the hot air bath gives more rapid results and lessens cinchonism. 4. Certain types of myocarditis seem to be benefited by the hot air bath. 5. Pilocarpin should never be used without the aid of hot applications to the body. So combined, there is no sialagog and less toxic drug effect, and far more sweating than otherwise. 6. Three cases of catarrhal jaundice were sweated; all the modern tests failed to disclose the presence of bile pigments in the sweat; only the epithelial debris containing bile deposits. 7. Modern sugar tests failed to reveal the presence of sugar in sweat obtained from diabetics. 8. A case of chronic constipation and indicanuria did not disclose the presence of indol or skatol in the sweat. 9. Regarding the function of eliminating normal and abnormal substances, the skin is not to be compared with the kidneys. 10. Free sweating seems to favorably affect the course of psoriasis. Lastly, 1,000 cc. of sweat contains about $11\frac{1}{2}$ gm. of solids, half inorganic and half organic; about 6 decigrams of urea, and about .47 centigrams of nitrogen. [C.A.O.]

5.—Transillumination of the Stomach.—R. C. Kemp calls attention to the internal administration of a fluorescent medium in order to enhance the action of the röntgen ray. The substances available as mediums are quinin bisulfate, horse-chestnut, and fluorescin. Kemp believes the use of fluorescent mediums to be a considerable advance in the technic of stomach transillumination, and the method with fluorescin to be an ideal one. [C.A.O.]

6.—Trunccek's Serum.—Swithin Chandler reports the results of the administration of this serum by mouth, 16 cc. being given twice daily. The serum gave fine results in rheumatism and arteriosclerosis, and he found it very useful in arterial hardening and tenseness in cases that require operation. [C.A.O.]

4. Two Cases of Severe Röntgen Ray Necrosis, Presenting Some Unusual Features. CLARENCE EDWARD SKINNER.
5. The Value of Vaginal Cesarean Section: With Report of Two Cases. M. STAMM.

1.—Administrative Control of Tuberculosis.—H. M. Biggs finds it difficult to understand the limited extent of sanitary procedures since the discovery of the etiology of tuberculosis. Only a small percentage of governmental authorities have adopted effective measures for dealing with this disease. Notification is necessary to any plan of supervision and yet a large proportion of the older physicians have opposed it. Notification does not require any action on the part of the authorities if it is reasonable to assume such action is unnecessary. If, however, the patient is poor, without a home, or living in lodgings, supervision is unobjectionable. To facilitate early diagnosis, free bacteriologic examination of the sputum should be afforded. Unfortunately in the absence of positive results from this, the nonexpert waits for more definite signs, thus losing valuable time. An important part of the duty of the sanitary authorities is in educating both profession and people as to this disease and its prevention. They should have the power of forcible removal and isolation of patients who are in such circumstances as to make them dangerous to those about them. The most troublesome problem which has to be solved is the following up of patients as they move from place to place and in seeing that the quarters they have left are properly disinfected. Suitable food should be provided by the authorities when not otherwise obtainable. Free dispensaries should be opened, hospitals maintained for advanced and sanatoriums for incipient cases. Regulations must be issued as to cases occurring in general hospitals, hospitals for the insane, penal institutions, asylums, public schools, factories, mercantile establishments, etc.; also as to spitting in public places. The latter is the keynote to the whole question of prevention of respiratory diseases. [H.M.]

2.—House Infection of Tuberculosis.—L. F. Flick considers that communicability depends almost entirely on the

house and that were it not for infection here the disease would soon perish from the face of the earth; sunlight, air and water being its natural enemies. The victim, on account of his chilliness, malaise and helplessness, ignorantly seeks the shelter of some enclosure. Primordially the bacillus was probably a saprophyte only and was evolved into a parasite by growing on tissue much debased. Even at the present time it does not seem able to invade until the tissue has been injured by malnutrition, traumatism or some other organism. Housed animals are very prone to the disease. For implantation prolonged intimate contact is necessary. With every one there is a minimal dose and by the natural mode of entrance this is larger than by inoculation. The best environment for implantation is first the home, and second the workshop. Hotels, public halls and conveyances in which people stop for a short time only are not apt to give rise to implantation except in the caretakers who are in these places much of the time. It is the accumulation of fine dust excluded from the bactericidal action of sunlight and air that makes the house dangerous. Both animals and human beings may go through life with tuberculosis and not be seriously inconvenienced by it. Life in the open air retards development and promotes recovery. [H.M.]

3.—Tetany.—J. Barsky reports a case in an infant of 11 months, in which it was the symptom ushering in an acute bronchitis. The treatment is purely symptomatic. For the rigidity there is nothing better than the warm bath. Pain is relieved by applying cold to the joints and giving bromid and antipyrin. If life is threatened from asphyxia, chloroform inhalations should be given. [H.M.]

4.—Röntgen Ray Necrosis.—Clarence E. Skinner reports 2 instances in which pronounced necrosis and sloughing of tissue occurred long after a prolonged use of the röntgen rays. The noticeable features in the first instance were: (1) Depth to which the original necrotic process extended; (2) "tanning" and excessive proliferation in spots, of epithelium of the new skin that was exposed by the peeling of that which had been browned directly by the ray; (3) cessation of the pain so soon as the necrotic tissue had separated; (4) favorable effect of the galvanic current in hastening the healing process after necrotic tissue had sloughed; (5) appearance of an area of necrosis 5 months after the last röntgen ray application, in a region which had previously exhibited no evidences that such injury had been inflicted. In the second instance the most marked feature was the appearance of an area of necrosis 6 months after the last röntgen ray application, in a region which had previously exhibited no evidence that such injury had been inflicted. The histories of these 2 cases constitute a warning against exposing a patient to the röntgen rays with even a moderate degree of frequency through long periods of time, no matter how well they seem to bear them at first. [A.B.C.]

5.—Value of Cesarean Section.—M. Stamm cites a number of cases of vaginal cesarean section from Duhrssen and other writers, and describes 2 from his own experience. The first was a case of eclampsia in which the patient had had 7 convulsions before seen by Stamm, and was in a comatose condition. The cervix, not obliterated, admitted the index finger, but as an attempt at further dilation with instruments would require too long a delay, vaginal cesarean section was performed. The incision was made the deepest in the posterior portion, and the child delivered in 6 minutes. The incisions were stitched up with catgut sutures. Two months later the patient was in perfect health, though a small portion of the posterior incision had not united. The child lived about $1\frac{1}{2}$ hours. The second case was also one of eclampsia with recovery of the patient. Stamm endorses Duhrssen's indications for this operation as follows: 1. Abnormal conditions of the cervix and lower segment of the uterus (carcinoma, myoma, rigidity, stenosis of the cervix and partial pouch-like distention of the lower uterine segment). Dangerous condition of the mother, which may be removed or relieved by prompt emptying of the uterus; affections of the heart, lungs, and kidneys. 3. Conditions of the mother where death is imminent and can be foreseen. The last 2 indications have value only in cases where the cervix is closed and not dilatable or where the depressing influence of labor pain should be obviated as in affections of the heart and lungs. In pregnancy complicated with cancer of

the uterus he advocates immediate vaginal section with subsequent extirpation of the uterus, no matter at what stage of pregnancy or at what stage of labor this condition is encountered. [W.K.]

CLINICAL MEDICINE

DAVID RIESMAN

A. O. J. KELLY

EDITORIAL COMMENT

Postdiphtheric Paralysis.—The progress of pathologic research continuously tends toward the diminution of the registered number of the respectably exclusive group of purely "functional" diseases. The social stronghold of the latter is now almost daily attacked by the irresistible engineering methods afforded by the use of the microscope, which follows that of the postmortem scalpel, and by the employment of experimental inoculation which follows suspicion of the presence of a specific poison. The most recent of the iconoclastic inroads upon the misty domain of "functional" pathology has been concerned with the interesting item of diphtheric paralysis. It is well known to all readers that in the early period which followed its recognition as a clinical entity, the various forms of those diphtheric lesions were regarded as the purest types of paralyzes *sine materia*—the best examples to be met with of the *asthenic* paralyzes of Gubler. This state of opinion prevailed down to the year 1862. It was, of course, based on the negative results obtained in the early autopsies. But it is now well known to the initiated that in the majority of instances in which careful postmortem examinations have been carried out by skilled hands, alterations of structure—more or less considerable in depth and superficial extent—have not failed to reveal themselves. Such lesions have engaged either the meninges, the cerebrospinal substance, or the nerves. The first skilled report of a meningeal origin of postdiphtheric paralysis was furnished by Humphey (in 1863), who published the details of the autopsy in a case of hemiplegia following diphtheria. He found a satisfactory explanation in the presence of a patch of meningitis covering the Rolandic area. Four years later (1867), Bühl reported the condition which he found in a fatal case of generalized diphtheric paralysis, the pia mater was honeycombed by localized extravasation of blood, which furrowed the subjacent cerebral cortex—some to a considerable depth. There were also found extravasations in the basal ganglions, the crura cerebri, pons varolii, medulla oblongata, and in the substance of the lobes of the cerebellum, and the centrum ovale of the cerebrum. The neighborhood of the hemorrhagic foci showed considerable softening, which involved in some degree almost the entire cerebral mass. The medulla spinalis was comparatively healthy, but the nerve roots, and the ganglions on the posterior one, were nearly double the natural size, and presented a dark red tint. Those changes were best defined in the lumbar region, and least in the dorsal. A case published by Oertel some years later (1871), in which death also followed generalized postdiphtheric paralysis, presented somewhat corresponding hemorrhages in the spinal meninges, especially on the right side, where they completely involved the roots of the nerves. The gray matter, especially that of the anterior cornua, was also riddled by small hemorrhagic foci. Oertel found on experiment, that corresponding conditions could be produced by inoculation. He inoculated pigeons with some of the matter of diphtheric exudation, and found intense meningeal congestion in one, and cell proliferation in the tunica adventitia of the medullary arteries in the other. Still, there was no evidence of actual paralysis in either case, and the conclusion arrived at was that the diphtheric virus displayed a kind of elective affinity for the vessels, especially those of the meninges and the nerve centers. Pierret and Maillard subsequently (1879) reported a case in which the autopsy

displayed a bulbomedullary meningitis, without appreciable lesion of the gray matter. It extended for some distance along the sheaths of the peripheral nerves. There was extensive leukocytic infiltration of the walls of the bloodvessels. Barth and Déjeuime reported in the following year (1880) the results of an autopsy in which there was found an annular meningitis, involving the lower part of the bulb and the upper portion of the spinal cord—from the plane of emergence of the hypoglossal nerves to that of the second cervical pair. The muscles of the velum palati were in a state of atrophy; their nerves showed evidences of advanced parenchymatous neuritis. Bühl had attributed the symptoms of diphtheria and of its consequent paralysis to the proliferation and accumulation of certain "cycloid bodies." They were developed in all parts of the economy, and their crowding round the motor nerve roots produced the paralytic symptoms. In fact, according to this observer, the symptoms were practically those of an anterior poliomyelitis, but, according to Sinclair, who made the microscopic examination in the case reported by Barth and Déjeuime, this explanation does not account for the symptoms of lesion of the sensory nerves which coexist. This observer regards the essential changes as the result of meningitis, or, more accurately, of a meningolymphitis. But, after all such interpretations have been discussed, and each has been allowed its own modicum of scientific recognition, the unquestionable fact remains that in many fatal cases of postdiphtheric paralysis no such meningeal lesions were found to exist. Accordingly, the true pathologic enigma of diphtheric paralysis still awaits its Edipus.

REVIEW OF LITERATURE

Buttermilk.—O. Rommel¹ has made careful observations concerning the value of buttermilk, and finds it an excellent and rapidly acting therapeutic dietetic agent in cases of acute gastrointestinal diseases and chronic metabolic disturbances. Its action is due to the small amount of fat, the very fine division of its casein, and the quantity of lactic acid it contains. The latter prevents abnormal fermentation and putrefaction of casein; it prevents late curdling and acts with the hydrochloric acid as peptonizing agent. Buttermilk cannot be used as a constant article of diet, as its lactic acid acts deleteriously on the metabolism of the body minerals, especially the amount of calcium. [E.L.]

Management of Epidemics of Contagious and Infectious Diseases.—J. S. Fulton² discusses certain general points that are of prime importance to all health officers. A health officer is handicapped from the start if for any reason his official character is seen in public only occasionally. It is very important that both health officers and the public be habituated to routine sanitary operations such as even the smallest districts require. A fact to be always kept in mind is that the American public is obedient enough to common sense and reason tactfully applied but refractory to coercion. From the beginning of his official life the health officer should make written notes of his daily work, however unimportant it may appear, and never leave the central authority unadvised of his operations. His official news should outstrip the service of the daily press. Fulton discusses procedures against the spread of infectious diseases under the following heads: Notification, inspection, immunization, isolation, quarantine, parole, disinfection. Notification must be in force all the time instead of reserved for epidemics. Fulton does not like the plan of placarding houses, and believes that a bulletin board at either end of the block, with the address of the patient in small letters, answers better in many ways. He doubts the wisdom of closing public schools when diphtheria has been discovered. Every throat in the school should be inspected and cultured, children from infected houses excluded, and those with reddened fauces sent home. The school can then continue with but little or no danger. [A.G.E.]

¹ Archiv für Kinderheilkunde, 1903, xxxvii, 252.

² Albany Medical Annals, November, 1903.

Typhoid Bacilli in Butter: An Experimental Contribution.—C. Bruck¹ performed 3 series of experiments: 1. Typhoid bacilli were added to milk and this churned to butter; the butter and buttermilk were tested separately; the length of time in which typhoid bacilli could be isolated was noted. 2. The vessels were washed with water containing typhoid bacilli, and milk for the purpose of churning, added. 3. Pieces of linen were soiled with typhoid stool matter; they were washed, and the water used for rinsing the churns. Butter made in these vessels was tested for typhoid bacilli. They were discovered in the butter after all 3 tests, although the water in experiment 3 contained but 16 colonies to the plate. The butter and cream were found to contain more colonies than the buttermilk. Typhoid bacilli were found present as late as the twenty-seventh day, and increased in number during the first few days. [E.L.]

Action of Adrenalin on the Absorptive Power of the Peritoneum.—The experiments of A. Exner² were made on rabbits, and consisted in the intraperitoneal injection of adrenalin, followed by certain poisons. He found that the adrenalin considerably retarded the absorption of such substances as strychnin, potassium cyanid, physostigmin, and indigo. Potassium iodid, however, was not influenced in this way. Further experiments showed that it is the absorption through the lymphatics which is retarded by adrenalin. It is, therefore, probable that potassium iodid and some other substances gain entrance into the blood directly by osmosis. Adrenalin also has considerable influence on the absorption of bacteria from the peritoneal cavity. This fact may be of practical use in the operative treatment of peritonitis. [B.K.]

Intestinal Origin of Tuberculosis.—L. Sorger³ announces that he has fed foxes for 6 months daily with fresh human tuberculous sputum without producing the slightest effect on them; neither tuberculosis nor deterioration of general health developed. Large quantities of the sputum were given in uncooked milk and raw beef. He concludes from this that foxes are immune against human tuberculosis, at any rate if the sputum is fed to them by mouth. [E.L.]

Should a Tuberculous Lung be "Exercised"?—It has been fashionable for a very long time, both with the laity and the profession, to advise lung exercises in cases of threatened or actual pulmonary tuberculosis. Norman Bridge⁴ says the suggestion that all this should be changed, and that we should stop purposely exercising the sick lung, that we might even sometimes put such a lung to rest completely, strikes the average mind as distinctly heterodox; to many it is the rankest heresy. When we examine the basis of the belief in deep breathing—really lung stretching—in tuberculosis, we soon find grounds for doubt. In the cases of recovery attributed to this exercise the deep breathing was only one of several agencies that might have contributed to this end. The contention for lung gymnastics and stretching in tuberculosis ignores many facts and grossly violates others. It is unreasonable to suppose that for many thousands, even millions, of years man and constructively all the mammalian animals have been breathing in the wrong way. Examples are given by Bridge to demonstrate not only that quiescence of the diseased lung is desirable for the sake of its healing, but also that mucopus in the bronchi does little harm. He concludes by stating that pumping and stretching the sick lung by useless and straining cough, by voluntary deep breathing, by devices of all sorts calculated to stretch the air vesicles, ought, in all cases of active pulmonary tuberculosis, to be abandoned completely. [A.G.E.]

The Struggle with Leprosy.—J. J. Hubert,⁵ discussing the measures adopted to limit the spread of leprosy, comes to the following results: The most efficient weapon in the struggle against the disease is unquestionably isolation of the victims. Whenever circumstances allow, private isolation with strict adherence to certain sanitary rules may be resorted to; otherwise, the leprosarium is the only safeguard. In both instances the needs of the patient should not be made subservient to

preventive measures, but rather should the two receive equal shares of attention. Since leprosy is communicable in all its clinical forms, isolation is required for all lepers, excepting those in whom the pathologic process has come to a standstill. Furthermore, isolation must be made compulsory if the spread of leprosy is to be sufficiently checked. While pleading eloquently for separation of the victims, the author does not lose sight of the justice and sympathy that we owe the outcast. [L.J.]

Inoculation of Monkeys with Bacteria from a Chancreoid.—E. Tomaszewski¹ infected a crown ape with pure cultures of streptococci derived from a chancreoid; they produced in this ape, ulcers which possessed clinically and microscopically all the characteristics of the chancreoid. Bacteria cultivated on blood agar from these sores were capable of again producing soft chancres in man. In a Java ape a similar ulcer formed, but pursued an abortive course. [E.L.]

Albuminuria of Puberty.—F. Lommel² had the opportunity of examining the urine of 587 young persons over a period of several years at about the age of puberty. Of these cases, 111, or 18.9%, showed a positive albumin reaction at least once. The test used was acetic acid and potassium ferrocyanid. The albumin was usually intermittent in its occurrence. It consisted mainly of nuclealbumin, with globulin. The amount rarely exceeded 1%. The cause of this condition is perhaps partly due to poor condition of the blood, and partly to a mild degree of cardiac insufficiency. The new formation of blood and growth of the heart do not keep pace with the rapid development of the rest of the body. The albumin of puberty may be diagnosed from that of nephritis by the absence of epithelial and granular casts, by the presence of a periodicity in the occurrence of the albumin, and by the absence of ophthalmologic signs of nephritis. Left-sided hypertrophy of the heart and increased arterial tension may occur in either condition. [B.K.]

Anastomotic Circulation of the Heart.—G. Galli³ is a defender of the statement that the coronary arteries are not end arteries and that there is a small artery connecting them. In support of this he quotes a case in which the orifice of the right coronary artery was completely occluded by sclerotic granulation tissue. The remainder of the vessel was pervious. In spite of this the right heart was perfectly well; the left ventricle showed a sclerotic patch. The explanation of the paradox was found in a branch connecting the left with the right coronary arteries, which thus prevented nutritional disorders of the right heart. [E.L.]

Studies of Gastrointestinal Catarrh in Infants.—C. E. Bloch⁴ has made a careful study of the gastrointestinal canal in 10 fatal cases of gastroenteritis in infants. He comes to the conclusion that there are, at least in some cases, decided anatomic changes. The existence of such changes has often been doubted, the reason probably being that macroscopically they are generally inconspicuous or invisible. Microscopic examination shows such changes to be present, both in the small and in the large intestine. As noted by Bloch, the changes differ somewhat in the acute and in the chronic cases. The morbid process involved in part the interstitial tissue, in part the surface epithelium and that of the tubules. In the more chronic cases, the chief feature was a round-cell infiltration of the interstitial tissue and also of the mucosa itself. In some cases, hyperemia and hemorrhages were found; in these the round-cell infiltration was slight, but there was evidence of serous exudation. In no case was there any fibrinous exudate, either in the tissues or on the surface. Slight ulcerations were present in some instances. The pathologic changes in the epithelium ranged from beginning degeneration to complete necrosis. The epithelium was degenerated only in the places in which the interstitial changes were marked. In every case only a small part of the intestinal canal was affected, the principal changes occurring in the neighborhood of the ileocecal valve. They extended for a short distance only into the small intestine, but more uniformly over the large. Occasionally the duodenum was involved. Former investigators found desquamation of the

epithelium over a large extent of the bowel, but this was probably due to the examinations having been made some time after death. Bloch injected formalin into the abdomen immediately after death, so as to preserve the structures from cadaveric change, and did not find any extensive desquamation. [D.R.]

Unusual Form of Gastric Ulcer.—M. Hayem¹ recently described at the Paris Academy of Medicine a form of gastric ulcer which had not been previously reported, and to which he gave the name of "mal perforans external of the stomach." This ulcer begins on the peritoneal surface of the stomach, and may be recognized in one of 3 stages: In the first there is a circular depression which resembles that made by the energetic application of a tampon; in the second it appears like a sac with the wall of the base thinned; in the third there is a cup-like depression with a colored base, due to hemorrhages. The mucosa, which is the only coat of the stomach remaining, appears as a hernia in the affected area. The first stage is not rare, and probably has not been described because it is considered of little importance. Hayem has found the second stage of the lesion 3 times, all in cases of chronic ulcer of the stomach. The stage of ulcer properly so-called has been seen but once, in a patient who died from a classic ulcer of the stomach. The field of the 2 varieties thus seems to be the same, but the processes are entirely different. [A.G.E.]

Diagnosis of Chronic Nephritis.—Schwarzkopf² reports 5 cases, in which without albumin, hyaline and granular casts were more or less plentiful. The patients in all instances showed some cardiac and arterial disturbance. In the histories of all of them alcohol and syphilis played an important part. He considers cylindruria without albuminuria an early sign of chronic nephritis, and believes it to be a most important point in the early diagnosis of a disease in which for therapeutic and prognostic purposes every sign should be welcomed. [E.L.]

Peculiarities of Temperature in Appendicitis.—W. T. Rostowtseff³ remarks that in this disease the temperature is very apt to show features which are unusual in other inflammatory visceral affections. Thus in about one-third of all cases, operation reveals pus, while the temperature has been low or falling. Several authors have observed that in appendicitis the difference between rectal and axillar temperature may reach 1° C. to 2.9° C. (1.8° F. to 5.2° F.), while in other diseases this difference amounts to 0.5° F. to 1° F. Again, in severe forms of appendicitis, there is often a disproportion of pulse and fever—a fall of temperature being accompanied by a rise of the pulse-rate. The highest daily temperature in appendicitis is frequently seen at a later hour than in other diseases, oftenest about 9 to 10 p.m. instead of 4 to 6 p.m. This shifting of the maximum is considered by the author as a *signum mali ominis*. [L.J.]

The Communicability of Bovine Tuberculosis to Man.—E. Schindler⁴ reports a case occurring in a man, whose occupation was the slaughtering of diseased cattle. This patient had cut each hand on 2 separate occasions, and, without taking proper precautions, had handled tuberculous cattle soon afterward. A typical tuberculosis of the skin followed each inoculation, and the lymphatic glands in the neighborhood of each elbow became enlarged. The tuberculin test produced a marked, local, inflammatory reaction and a slight general reaction. The enlarged glands were excised, and their examination revealed numerous, characteristic giant-cell tubercles. [B.K.]

A New Quantitative Method for the Determination of Sugar in Urine.—As diabetic urines containing organic iron compounds cannot be titrated accurately with Fehling's solution on account of the simultaneous formation of Berlin blue with the brown ring of potassium ferrocyanid, E. E. Schmidt⁵ proposes a new method which depends for its principle upon the reducing action of its glucose on an alkaline basic bismuth nitrate (Nylander's) solution. By testing it he found that 3.7 cc. of a definite bismuth solution, the formula of which he gives,

reduces 1% sugar, or that each cubic centimeter of the solution corresponds to 0.27% of sugar. Several other quantitative methods easy of application and comparatively accurate of result are discussed. [E.L.]

Tetany in a Patient Suffering from Gastric Cancer.—J. Burnet¹ gives the notes on a case of gastric cancer, with extension to the liver, in which tetany occurred the day before death. The patient was a woman of 50 who had had symptoms of pyloric obstruction for some time. She had been kept under the influence of morphin for many weeks. In connection with the occurrence of tetany, Burnet emphasizes 3 facts: 1. The case was one of involvement of both stomach and liver. 2. The patient was taking considerable morphin daily. 3. There was the history of a family quarrel some 3 days before the onset of tetany. Burnet's impression is that the quarrel, which affected the patient very much, was the real cause of the onset of tetany. If the close relationship of the nervous system to the organs of alimentation is borne in mind, there is not much difficulty in explaining why tetany should result in cases where the stomach is irritated as it undoubtedly is when it is dilated or the seat of malignant disease. Without discussing the various theories regarding the origin of tetany in gastric disease, Burnet publishes his case in order to induce others to do likewise. Thus the true incidence of the condition may be determined. [A.G.E.]

C. A. ORR

EDITORIAL COMMENT

Suture of Bloodvessels and Possible Restoration of Amputated Extremities.—The frequency with which disastrous results followed ligation of main arterial and venous trunks, early led to attempts to avoid tying larger vessels in case of injury. Although statistics of the results of such operations have greatly improved since the introduction of aseptic surgery, it is often an important question whether we can deal with a severe injury, or some pathologic condition involving the great vessels, without suddenly cutting off the blood-current which nourishes a large part of the body.

Höpfner² gives an interesting paper on this subject, based on a series of experiments in arterial suture on dogs, with a review of the literature from the earliest times up to the present date and with a bibliography of 82 references. He refers to the work of Hallowell, who in 1759 successfully arrested hemorrhage from an injured brachial artery by suture, and of Lambert, of New Castle, who in 1762 experimented with arterial suture on horses and was able to obtain satisfactory closure. Arterial suture was tried with varying success and many complete failures until the introduction of antiseptic surgery. Even as late as 1890 some surgeons of authority opposed attempts at arterial suture. From that time on suturing of vessels was frequent and the results for the most part favorable, so that in 1892 Schade was able to report 30 cases. The first successful circular suture of one of the great bloodvessels was by Murphy of Chicago, who in 1897 excised a portion of the femoral artery and closed the vessel by the invagination method. The operation was undertaken for the repair of a gunshot injury to the artery just below Poupart's ligament. Payr, of Graz, has recently performed circular suture successfully with the use of supporting absorbable rings of magnesium. In this way he is able to bring intima in contact with intima. Höpfner reports six experimental sutures by Payr's method, with two unfavorable results from thrombosis. Finding that he was able to suture bloodvessels successfully, he attempted the resection of a piece of the common carotid artery 4.5 cm. long; he turned this piece end about and sutured it in place; the recovery was uneventful and four and a half weeks later he found the wall of the vessel thickened and surrounded by scar tissue, but with no special change within the lumen of the vessel. His next attempt was the interchange of sections of two different arteries in the same animal. He was able to remove a section 3 cm. long from the carotid and femoral arteries and substitute the one for the other successfully. Both vessels healed and perfect function was retained in each. Attempts at transplanting sections of vessels from one animal to another of the same species also resulted successfully, but on attempting to substitute sections of vessels from different animals failure resulted in every case. The vessels substituted were taken from cats and rabbits and transplanted into dogs,

but in all cases, even when the healing of the wound was perfect, the foreign tissue was entirely absorbed. Höpfner then tried amputation of the hind leg of a dog with immediate suture into place again in three cases. The smaller vessels were tied and the larger vessels and nerves were sutured. In two cases thrombosis and gangrene resulted, while in a third case the dog was in good condition with free circulation at the eleventh day after operation, when he died from anesthesia given in order to make the first dressing without struggling. In summing up the results of his work Höpfner speaks confidently about the possibility of suture of large vessels and of transplantation when sections of vessels are destroyed by injury or in cases in which it is necessary to resect a considerable section of a blood-vessel in operations for excision of large tumors. Transplantation of large veins is not to be recommended as a rule, and if this is undertaken the section inserted should be placed so that the valves are properly placed with the blood-current. The restoration of extremities which have been completely or almost entirely amputated he considers possible, though the difficulties are great.

Everyone now recognizes the perfect feasibility of suturing the large bloodvessels and of restoring amputated fingers, in many cases, but in successfully transplanting sections of large vessels and restoring entire extremities Höpfner has, so far as we know, taken a step in advance of any previous investigator. We doubt if this will prove to have as great practical value as the recent work of Matas in the treatment of aneurysm by arteriorrhaphy, but the subject at least deserves further experimental study. Many may look upon these experiments as unjustified and not see in the successes obtained any justification for further attempts of this kind. We feel that it is entirely too early to express an opinion as to what the development in this line will be during the next decade. Very many operations which were unheard of 25 years ago are now successfully performed, not only by masters of surgery, but by surgeons of practically every city and town. We do not believe that we have, by any means, reached the limit of things possible in surgery, though in just what direction the achievements will be made it is difficult to predict. If in the future we find ourselves able to transplant sections of large vessels successfully many valuable limbs and lives will be saved and the results of serious, unavoidable accidents will be much less appalling.

REVIEW OF LITERATURE

Wounds from Blank Cartridges.—D. P. Allen and A. I. Ludlow¹ report clinical observations upon 16 cases cared for at the Lakeside Hospital, Cleveland, with a bacteriologic report upon several of them. Among the cases was 1 wound of the abdomen, 1 of the scrotum, 1 of a finger, and 13 of the hand. None of the cases treated primarily in the hospital by excision of the wound under ether, careful disinfection and packing with iodoform gauze, developed tetanus. Most of these had been dressed previously but only by bandages. Five cases developed tetanus, all ending in death. The wounds occurred on July 4, 1903, the lacerations being relatively greater than those of previous years, this showing the increasing power of the explosives used. The injury to the deeper structures was always greater than the superficial wound would indicate. Another factor of importance is that serious symptoms did not develop at once after the injury was received. Such wounds may remain quiescent for some days, giving rise to no apprehension. Inoculations from 5 cases which did not develop tetanus proved sterile in 3. In the other 2 were streptococci and staphylococci. In only 1 case of the 5 which developed tetanus was the tetanus bacillus found. In 4 of them *B. aerogenes capsulatus* was found. Ludlow states that as the influence of light is destructive to tetanus bacilli, the influence of the röntgen ray upon their growth should be determined. Allen says that medical bodies should point out in an authoritative way to governing boards of cities that manufacture and use of toy pistols should be absolutely prohibited. [A.G.E.]

Migrating Phlebitis.—E. Niesser² removed from the superficial veins of the arms of a man 3 spindle-shaped nodes, which were painful on motion and pressure. Microscopic ex-

amination showed inflammatory proliferation, chiefly of the media and adventitia. There was nothing resembling thromboses. Shortly after the operation 3 new nodes appeared. In spite of the absence of other syphilitic symptoms, mixed treatment was ordered, and the nodes disappeared very rapidly, proving the case to have been one of syphilitic phlebitis. [E.L.]

Anesthetics in Rectal Diseases.—R. W. Lloyd¹ thinks colotomy cases should be put on a beef tea diet. With an unusual amount of cough, congestion, cyanosis, or secretion from ether, it is well to change to chloroform. For anal fissure and fistula, gas and ether have proved excellent. Should tubercle of the lung be present and the ether be found irritating chloroform may be substituted. Somnoform is unsuitable for most rectal cases but may be used as a preliminary to chloroform as it induces anesthesia in a minute or less. For colotomy it is well to begin with ether, changing to chloroform if there is much movement of the abdominal wall. With local anesthesia only the patient may shrink and by drawing in the anal region prevent access to the parts, and there may be more pain than anticipated. The amount of cocaine should be limited to a grain. Eucain may be used more freely. Anestile, a mixture of ethyl and methyl chlorid is the best local anesthetic in opening abscesses. [H.M.]

The Value of Tuberculin in Surgical Diagnosis.—M. B. Tinker³ makes a valuable practical contribution to this question, his paper being based on a study of the results of injections in 400 cases at the Johns Hopkins Hospital where Dr. Halsted has had the test applied to most surgical cases suspected of tuberculosis since 1896. The most important questions to determine are whether the use of tuberculin is harmful, and if it is reliable. The experience of 7 years at the hospital has led to the belief that in the small doses needed and under proper conditions, the injection of tuberculin for diagnostic purposes is not attended with danger, and should not give rise to serious or distressing symptoms. The reliability of the test was satisfactorily demonstrated. It was perhaps of greatest value in cases in which there was doubt as to whether they were dealing with hysteric, traumatic or rheumatoid disease of the joints or with an early stage of tuberculosis. The tuberculin employed was obtained from Dr. E. L. Trudeau, of Saranac Lake. The minimum dose was at first 0.002 gm., but with a new supply of the material, the dose was increased to 0.003 gm. If no reaction is obtained from this dose, the amount is increased to 0.006 gm. or 0.009 gm. The injection is made deeply into the deltoid muscle. Sex seems to have but little influence on the reaction. The dose should not be proportionately smaller in children. Tinker suggests a possible cause of the reaction to tuberculin. Toxins are being constantly produced by the tubercle bacilli in the body, but if the foci are small the toxin is neutralized by the body without allowing them to produce constitutional symptoms. If tuberculin be injected neutralization is not possible, and the temperature rises. In cases where the toxins are produced in large enough quantities to cause constitutional involvement with increased temperature, the addition of a small amount of tuberculin will not cause sufficient increased reaction on the part of the individual to produce a further rise of temperature. [A.G.E.]

Hepatic Cirrhosis and Angiocholitis.—G. I. Volintseff⁴ emphasizes the surgical importance of these conditions. Unfortunately, operative treatment of cirrhosis has fallen into some disrepute. While hepatic cirrhosis without angiocholitis requires only medical treatment, operation is called for when fever and pain persist in spite of mere clinical measures. The main difficulty lies in differential diagnosis, since no definite picture corresponds to cirrhosis, to angiocholitis, or to gallstones. An infectious cholecystitis may produce the same symptoms as stones in an inflamed bladder. Intermittent fever speaks for a catarrhal process in the gallbladder and ducts; continued fever rather indicates suppuration. The latter condition also produces more marked hepatic insufficiency than the catarrhal process. A circumscribed purulent angiocholitis may end in resolution without operation; on the other hand, a

⁴ Johns Hopkins Hospital Reports, Vol. xi, 1903.

⁵ Russki Vrach, October 25, 1903.

general suppurative process indicates surgical interference. In all cases of inflammation of the bile ducts the blood-serum should be examined for biliary pigments. [L.J.]

The Frequency of Carcinoma in Munich.—O. Bollinger¹ has collected and studied the cancer statistics of Munich for the last 50 years. He does not find that cancer has increased in frequency during these years, nor has its mortality become greater. The cases and deaths have simply paralleled the growth of the population and not exceeded it. He believes the reasons for an apparent increase in other cities to be: Greater duration of life, improvement in methods of diagnosis and increase in number of autopsies, thus leading to the discovery of a number of cases of carcinoma clinically latent. He adds to his paper an argument against the infectious nature of cancer. Ordinarily infections are very prevalent before the age of 20; why cancer, if it is of parasitic origin, should attack people of advanced years and leave unscathed children and young adults, he cannot conceive. [E.L.]

Bullet Extracted from the Wall of the Heart.—This case was recently reported to the Paris Society of Surgery by M. Tuffier.² The patient was an officer who received a pistol wound in the second left intercostal space. He remained on his horse for half an hour when he was seized with violent oppression. This passed away and finally the external wound healed. After some time there appeared symptoms referable to the heart and a radiograph showed a foreign body superficially on the left wall of the heart and having the movements of that organ. A portion of the second left costal cartilage was removed, the finger introduced under the border of the lung and the foreign body finally located. The overlying tissue was carefully denuded and the ball extracted. The patient suffered a slight oppression following the operation, but made an uneventful recovery. [A.G.E.]

Radical Operation in Inguinal Hernia.—After discussing the frequency of inguinal hernia in Japan, T. Honde³ describes the method he employs for its radical cure. He has modified Bassini's method as follows: After removal of the hernial sac, he introduces his finger into the internal ring and separates the transversalis fascia from the peritoneum for a distance of about 3 cm. (1½ in.). The ends of the silk thread used for ligation of the sac are carried through this space, and brought forward through the entire thickness of the abdominal muscles, and tied external to the external oblique aponeurosis. His statistics vie with the best. In femoral hernia he employs the same modification. [E.L.]

Rizzoli-Esmarch Operation for Ankylosis of Mandible.—J. A. Presno y Bastiony⁴ gives the interesting result of this in the case of a child of 8, in whom, after having an attack of measles 4 years ago, occurred a gangrenous process of the lower jaw. Treatment of various inefficient kinds had brought about an ankylosis. Esmarch conceived the idea of a linear osteotomy about the cicatrix at the joint. Rizzoli modifies this to a cuneiform resection. In this instance, after operation the child was able to masticate with ease. [T.H.E.]

Cocainization of the Spinal Cord Combined with Adrenalin.—Acting upon Braun's conclusions that adrenalin diminishes the toxicity of cocain and increases its anesthetizing property regarding length of time and intensity, A. Doenitz⁵ performed some experiments to prove the truth of these conclusions when cocain is used intraspinally. He employed cats for experimentation; they die ordinarily when 0.018 gm. (¼ gr.) is injected. Preceding the cocain injection with an intradural injection of 0.5 cc. of a solution of adrenalin, 1 to 1,000, the cats were able to bear as much as 0.1 gm. (1½ gr.) of cocain; injecting the 2 simultaneously, 0.06 gm. (1 gr.) of cocain was tolerated. The adrenalin itself is but very slightly injurious, as proved by personal experience. That it also increases the anesthesia is shown by the fact that anesthesia is produced by much smaller quantities of cocain than usual; from 0.0075 gm. to 0.015 gm. (⅓ gr. to ½ gr.) were sufficient for even major operations. Doenitz believes that this solves the question of

spinal anesthesia and prophesies the time when general anesthesia will be abolished. [E.L.]

Primary Resection of Intestine in Gangrenous Hernia.—A. Martina,¹ writing from Payr's clinic, reports 36 cases of strangulated hernia (22 femoral, 12 inguinal, and 2 umbilical). The incarcerations lasted from 1 to 9 days. Sixteen were operated upon with the Murphy button method, 20 with primary resection and suture; 3 of the former and 4 of the latter died. Since 1899 the latter operation was performed almost wholly, no matter how serious the condition, while previous to that period an artificial anus was made in all dangerous cases. The author considers the results since 1899 better than before that period, and therefore advises in all cases where a skilled surgeon and assistants can be had, primary resection and suture, no matter how grave the case. In country practice it may become necessary, in grave cases, to establish an artificial anus. [E.L.]

Surgical Treatment of Fractured Spine.—C. H. Rodi² reports 4 cases to illustrate the value of surgical treatment of fractured spine. He believes it to be the duty of the surgeon to operate in every case, as almost any risk is justifiable when the hopelessness of spinal fracture when untreated is taken into consideration. Even in traumatism of the spine associated with paraplegia, operation is indicated to determine if the paralysis is not due to bony pressure incapable of spontaneous relief. The operation should be deferred no longer than recovery from the original shock may demand. One of the cases reported is believed to corroborate the results obtained by Stewart in a case of severed cord. The injury in this case was due to falling rock, the fracture and dislocation being at the tenth and eleventh dorsal vertebrae. The cord was found to be completely severed with the exception of a strand the size of an ordinary pin. Sensation was present below the pelvis on the day following the operation and in the ankles at the end of a week. One year after, the patient could evacuate his bladder every 8 hours; had voluntary action of the bowel, though constipated; could stand alone with hand on table, and hobble about with the aid of crutches. He was improving constantly and looking forward to complete recovery. [A.G.E.]

Intravesical Separation of the Urine of Both Kidneys.—Keydel³ reports 25 cases, 4 of which were his own, in which the Luys or Cathelin vesical segregator were employed with success. These instruments push the vesical floor downward and separate the bladder into 2 compartments by means of a hard rubber membrane. The results which he reports were absolutely satisfactory and superior to the results which are reported with urethral catheterization. [E.L.]

Colopexy in Prolapse of Recti.—J. Rotter⁴ prefers colopexy in extensive rectal prolapse to resection, as the latter presents considerable danger, may leave strictures at the point of operation, and is followed by relapse as often as the former. When colopexy is performed by suturing 2 serous surfaces together, the union cannot of necessity be very firm. To produce good fixation he sutured the rectum in one case to the muscles of the abdominal wall, bringing it through the peritoneal incision; in another case he sutured the sigmoid flexure to the cellular structures of the false pelvis. In both cases the final result promises to be very good. [E.L.]

Operation for Strangulated Hernia in a Man of Ninety-seven.—G. R. Curran⁵ reports this case. Owing to irregularity of the heart the strangulated inguinal hernia was operated upon under local anesthesia. The operation was performed on an old pine table in a log cabin, with numerous flies about. The patient quickly recovered and soon after celebrated his ninety-seventh birthday. [A.G.E.]

Mesenteric Openings as a Cause of Intestinal Obstruction.—W. N. Orloff⁶ has made a series of clinical experiments on dogs in order to show the role of mesenteric openings in causing obstructions of the intestines. Usually these openings have been considered as productive of internal incarceration, not obductory obstruction. The author's experiments seem to

justify the following conclusions: 1. Intestinal coils, having become caught in the mesentery, do not, as a rule, cause obstruction, unless incarceration or twisting of the intestine takes place. But even if symptoms of obstruction are produced, the offending coil may yet disengage itself during the violent peristalsis. Repeated attacks of transitory intestinal obstruction are probably often due to this very circumstance. [L.J.]

Congenital Malignant Tumors.—E. Joseph¹ reports 2 of these rare tumors in children. (1) In a child of 15 months a mass developed, which upon operation was found to be a tumor involving the entire left kidney. The kidney was removed and the child recovered. Histologic examination showed it to be a mixed tumor. Additional points of interest in the case are, absence of metastases and no recurrence 18 months after. (2) From the abdominal wall of a 5-months' old child an embryonal tumor was removed, which had undergone sarcomatous degeneration. [E.L.]

Anatomic Criticism of Total Prostatectomy.—Cuthbert S. Wallace² gives a detailed description of the normal prostate, likewise of pathologic specimens of the enlarged organ and its relation to the bladder, removed postmortem. His conclusions are that the usual form of prostatic enlargement is an adenomatous one; that the adenomatous tissue may surround the urethra or form masses in the lower parts of the organ behind the urethra, or in all three parts; that the parts removed may consist of adenomatous masses in the lower parts or of an adenomatous formation completely surrounding the urethra; that there is always left behind a definite laminated envelope containing glandular tissue derived from the extended outer portion of the organ; that the amount of envelope left on the surface of the tumor, after removal, depends on the depth at which the enucleated finger cleaves the envelope; that the rectovesical fascia is not opened nor the prostatic plexus of veins injured at operation; that though it is possible to remove a small adenoma from the center of the lower part of the prostate without extensively injuring the urethra, yet this canal is removed *in toto* when the adenomatous growths are extirpated in their envelope. The lateral walls come away adhering to the adenomas, and these are of considerable size. He suggests that the term "surgical capsule" should be applied to the outer envelope formed from the prostate by the extension of the adenomas. This represents more than the outer nonglandular portion to which Shattock has given the name of cortex. To its presence is due the small amount of bleeding and absence of urinary extravasation. The enucleating finger never goes outside, therefore cannot injure the rectovesical fascia. [A.B.C.]

GYNECOLOGY AND OBSTETRICS

WILMER KRUSEN

FRANK C. HAMMOND

REVIEW OF LITERATURE

Postpartum Infection of the Uterus.—Chief among the bacteria of puerperal infection are the streptococcus, gonococcus, colon bacillus, and the saprophyte. The saprophyte never attacks the living cell or invades the deeper structures of a healthy organism. The streptococcus is the most deadly of these germs, and in contradistinction to the other germs, it may and does proliferate in living tissues, and is the only one which jeopardizes life, though the others may produce invalidism. Hence the importance of distinguishing between streptococcus infection and that of other germs, and this can be done positively only by microscopic investigation. But when this cannot be had, clinical evidences must be depended upon, and it may be stated as a rule that putrid infection is characterized by high temperature, slow pulse, and foul odor; whereas in streptococcal infection there is no odor in the earlier stages, and the pulse is markedly accelerated according to the virulence of the infection. Digital examination of the uterine cavity will also give valuable evidence. In putrid infection the uterine cavity contains debris, whereas in streptococcus infection the

mucosa may be perfectly smooth. According to D. Tod Gilliam¹ the normal deathrate for puerperal infection is about 1 in 100, but in streptococcus infection alone it is 1 in 25. The safeguards against infection are autosterilization of the genital tract, the uterine mucosa, and the massing of germicidal leukocytes beneath the epithelium. [W.K.]

Vaginal Operation without Anesthesia.—J. V. Frommer² reports 3 cases having undergone vaginal operations without any general anesthetic because of strong contraindication. Two were aged 69 and 77 years. Anterior colporrhaphy and amputation of the portio were performed in the former, sclerosis of the arteries being the contraindication; and the latter underwent vaginal hysterectomy for carcinoma without anesthesia because of myocarditis. The remaining case was that of a woman, of 34, with insufficiency of the mitral valve, and operated upon for erosion of the cervix; both lips of the cervix were excised followed by colporrhaphy and rectocelorrhaphy. In regard to the patient of 77, he remarks the sensibility during the operation was so slight that she only groaned twice. There was satisfactory recovery in each case. On the ground of these experiences Frommer recommends where general anesthesia is contraindicated, to operate without it, with the help of local anesthetics. Also in each case a half hour before the operation he used a small injection of morphin which tranquilizes the patient. As a local anesthetic he recommends the injection of a weak Schleich's solution into the perineum and the region of the vulva before operating; and he considers the injection of this into the connective tissue of the ligaments and tubes before ligation as superfluous. [W.K.]

A New Operation for Cancer of the Uterus.—M. A. Strauch³ recommends a modified radical operation of his own which has given him excellent results in 20 cases. He describes his method in these words: The surgeon thoroughly scrapes out the cancerous tissues with a sharp spoon—or, if feasible, cuts off the growth with scissors. The resulting excavation or raw surface is then well cauterized with the Paquelin. The vagina is tightly packed with iodoform gauze in order to check the hemorrhage and raise the uterus as high as possible. Thereupon the patient is placed in the Trendelenburg position and the linea alba incised from navel to symphysis. Bleeding vessels are clamped with Kocher's clamps, and the fundus uteri is grasped with strong Muzeux forceps and lifted high up. The infundibulopelvic and the round ligaments are ligated with strong catgut as far as possible from the uterus, and besides, Kocher's clamps are inserted nearer the uterine body in order to prevent bleeding into the peritoneal cavity. With scissors the surgeon now cuts the upper portion of the broad ligament and separates bluntly the two folds. This exposes to view the lateral ligament, showing the ureter in the depth, and just above the ureter is the uterine artery, which is ligated on both sides near its union with the hypogastric artery. The anterior uterine surface is separated from the peritoneum, the bladder and vagina being pushed high upward. The rectouterine ligaments are seized near the pelvic wall with Kocher's clamps and severed. The peritoneum of the Douglas space is opened and the rectum separated. When all this has been done the uterus remains connected only with the vagina. The latter is now cut off at a good distance from the uterus, and the anterior vaginal wall united with the apex of the bladder, leaving the peritoneum free. The posterior vaginal wall is united to the posterior fold of the peritoneum. The glands at the obturator nerve and at the inner inguinal ring are removed. The peritoneum is also opened along the course of the large vessels and all glands excised. The subperitoneal space is drained from the vagina with 2 narrow strips of gauze. The abdominal incision is closed with a 3-story suture of catgut, together with a few silk sutures. [L.J.]

Thrombosis of the Femoral Veins Following Aseptic Laparotomy.—E. R. Secord⁴ reports the case of a woman, aged 35, operated upon for double hernia; that on the left side had been present 12 years, during which she had worn a truss, but the right hernia had existed only a few weeks, was gradually

¹ Deutsche medizinische Wochenschrift, 1903, xxix, No. 35.

⁵ Russki Vrach, August 30, 1903.

⁶ American Gynecology, October, 1903.

enlarging, and caused considerable pain. The early convalescence was uneventful, but near the close of the second week pain in the left groin led to an examination, showing a hard, indurated, tender cord occupying the position of the upper end of the long saphenous vein. A rise in temperature followed, with increase in pulse-rate. The condition was an extensive venous thrombosis involving the saphenous and femoral veins, following 2 weeks after an aseptic operation, with typically aseptic wound healing. It was on the left side where the smaller operation was performed, but where a truss had been worn for 12 years. Secord reviews the reports of several authors, notably that of Schenck, 58% of whose cases of thrombosis occurred after the removal of tumors. He also estimates that of the cases reviewed, in 73% the thrombosis followed operations which lessened local tension. His conclusions are: 1. No single etiologic factor is alone responsible for this complication. 2. The role of infection, in otherwise noninfected cases, does not appear to be an important one. 3. Conditions of sudden decrease of pressure dependent on the operation probably exert a causative influence. 4. Treatment should be prophylactic, by avoiding unnecessary traumatism, hemorrhage, or a sudden decrease in tension, by having the wound area well supported by firmly applied dressings. 5. So far as he is aware, there has been no mortality in the reported cases, but the occurrence of pulmonary embolism in a certain proportion warns us that this termination is not impossible. [W.K.]

Diseases Cured by Stem Pessaries.—J. H. Carstens¹ recommends the use of the stem pessary in the following kinds of cases: Infantile and poorly developed uteri, amenorrhea, scanty and irregular menstruation, as found in fleshy women; simple cases of retroversion in young girls, cases of stenosis or tortuous uterine canal. The stem must be worn at least 6 months. A year or even 2 years is better. If any irritation is produced, the pessary can easily be removed. No after-treatment is necessary, not even douches need be given. There must be absolutely no inflammatory pelvic trouble, either acute or latent. If there is ovarian or tubal trouble, other treatment or operation is necessary. His theory of the action of the stem pessary is based on the physiologic development of the muscles by exercise. Poorly developed muscles can only be made strong and large by exercise. As the tendency of the uterus is to expel all foreign substances, it exercises to get rid of the stem pessary, and thus it gets strong and large. [W.K.]

Overdistention of the Walls of a Gravid Bilocular Uterus.—J. Jurinka² gives the history of a woman, aged 32, who complained of severe, persistent pain in the right pelvic region. From a diagnostic point of view the severe pain was the strong indication for operation. Median laparotomy was performed and the uterus with the right adnexa amputated. Examination of the specimen showed the 2 halves of the uterus irregularly developed. The left half, normal in form, was enlarged and the cavity, 7.5 cm. (3 in.) in length, was filled with a decidual growth. The right half was much larger and contained a 14-weeks' well-developed, male fetus, 12 cm. (5 in.) in length; and while the walls of the left cavity were 20 mm. ($\frac{3}{4}$ in.) in thickness, those of the left were in some parts only 3 mm. to 5 mm. ($\frac{1}{4}$ in. to $\frac{1}{2}$ in.). This overdistention of the uterine wall was undoubtedly the cause of the severe pain and the radical operation was justified as preventing a repetition of pregnancy under such dangerous conditions. [W.K.]

The Mischievous in Midwifery.—W. P. Manton³ considers some of the everyday conditions incident to pregnancy, labor and the puerperal state, in which mischievousness in practice or neglect is of common occurrence. First is the failure to exercise a systematic supervision of the patient during pregnancy. At least monthly examinations of the urine, microscopic as well as chemic, should be made from the beginning of pregnancy until term. When threatening symptoms intervene, the induction of premature labor should not be postponed too long. Manton is convinced that many lives are lost annually because of lack of courage on the part of the physician to resort to vigorous measures sufficiently early in the presence of imperative symptoms. Diet, clothing, exercise, and rest

during gestation are of the greatest importance to the future mother, but are generally considered too trivial to elicit the careful attention of the physician. [A.G.E.]

Pathology and Treatment of Gonorrhea in Women.—A. P. Stoner¹ says: In the human body the gonococci may lie dormant for years and then produce virulent infection, though in the majority of cases after the infection has existed for a certain length of time the gonococci disappear spontaneously. This is accounted for by the displacement of the cylindrical epithelium by the pavement variety, which is more resistant and it is at this stage that treatment avails most. The urethra offers the most fertile soil for these microorganisms, next the uterine cavity beyond the cervix. This once invaded, the tubes rarely escape. The vaginal tract is the most resistant to all infections, as germs are killed by the secretions of the vagina in its normal state. During the early stages of gonorrhea cleanliness and rest should be procured. Vaginal douches are often harmful, in that they spread the disease. Pus formed in the urethra of a previously healthy woman is an almost certain sign of gonorrheal infection. If examination of vaginal discharges proves negative, douches are contraindicated and treatment should be directed wholly to the urethra and vulva. A pad of absorbent cotton should be snugly tucked between the labia and changed as often as soiled, and the outside parts doused with tepid water. After the second week a 2% to 4% solution of protargol, or a 15% solution of argyrol may be instilled into the urethra. Should the infection extend to the uterus a general siege now begins, which usually ends by the intervention of the surgeon and the entire removal of the diseased organ. If the tubes and ovaries have to be removed, the writer believes in removing the uterus also, especially in gonorrheal infection. [W.K.]

Should the Uterus and Ovaries be Removed in Operating for Double Pyosalpinx?—C. C. Frederick² thinks that a woman who has a pair of pus tubes is an invalid, and that in such cases both tubes should be completely removed, that it is unsurgical to leave any part of a diseased tube. With both tubes removed the woman is sterile, but so she was before the operation. The rule should be to save as much healthy ovarian tissue as possible. In some rare instances the uterus should be taken out also, for instance, if the condition is tuberculous the uterus should certainly be extirpated. But even if both tubes and the uterus are taken, leave the ovaries in whole or in part, if possible; but in double pyosalpinx remove the tubes in toto. [W.K.]

Cesarean Section in Eclampsia.—Westphal³ thinks that by cesarean section in eclampsia one avoids the long and dangerous delay required for the completion of induction of labor; the danger of injuring the adjacent parts and the danger of infection. He also regards it as easier and less dangerous than perforation or high forceps delivery. [W.K.]

TREATMENT

SOLOMON SOLIS COHEN

L. F. APPLEMAN

E. LINDAUER

REVIEW OF LITERATURE

Cold in Ocular Therapeutics.—Scrinii⁴ states that applications of cold in ocular therapeutics are much more restricted than those of heat. Two methods are usually employed: The first consists in applying to the eye, the lids being closed, small pieces of aseptic, absorbent cotton or gauze which have been dipped in cold sterile water, to which some mild antiseptic may be added. These should be renewed frequently; in the presence of profuse suppuration they should not be left in place long enough to become warm. When the inflammatory reaction is not so marked the compress may be cooled by allowing the water to fall on it drop by drop at frequent intervals. A much inferior method of applying cold is the use of an ice-bag, or Leiter's tubes. The ice-bag has the disadvantage

¹ American Journal of Obstetrics, November, 1903.

² Zentralblatt für Gynäkologie, November 7, 1903.

⁷ Journal des Praticiens, Vol. xvii, No. 42, 1903, page 659.

of causing uncomfortable pressure and its cooling action decreases as the ice melts, so that it is necessary to watch it constantly, which is not always possible. In using Leiter's tubes, the patient must be perfectly quiet, or they will become displaced. Beside, the prolonged application of intense cold is disadvantageous when the cornea is involved in a suppurative process, as it tends to decrease the already lowered vitality. Cold is used principally in the treatment of purulent ophthalmia of the newborn, gonorrheal ophthalmia of adults, and in purulent inflammations, associated with edematous swelling of the lids and chemosis. It is valuable in burns, in traumatism of the lids and globe, by calming the pain, and especially in preventing the inflammatory reaction, which is often intense. Goldzieher believes that cold favors the absorption of recent intraocular hemorrhages. The application of cold is contraindicated in diphtheric conjunctivitis. [L.F.A.]

Exercise as a Preventive of Gout.—According to J. K. Mitchell¹ it is as a preventive of gouty outbreaks rather than as a remedy for the affection, that exercise is valuable. But to this end it must be constantly and not spasmodically used. The hard-drinking men of former days kept off the gout, possibly unintentionally, by the active lives they led, in spite of their excesses in the matters of port wine and madeira. When they traveled they rode hard-trotting hacks or drove in a gig over rough roads, and hunting and shooting were their daily sports or, often enough in this country, their daily bread. Free water-drinking, a diet restricted in quantity as well as in character, and daily exercise sufficiently active to cause sweating and long enough continued to be moderately fatiguing are the only prophylactics. The tastes of the patient may be consulted as to the form of exercise, only the work must be distinctly active, and on occasion even severe, like tennis, a bout at hand-ball, 10 miles on a hard-trotting horse, or 20 minutes with a lively opponent at tossing a medicine ball. It must be done daily, or at least often enough to keep the victim of hereditary gout in fair training. The gouty patient who suddenly begins to take strong exercise without preparation may have an attack brought on by the exertion; and the same thing occasionally occurs when one abruptly ceases hard exercise. In the former case the result is probably due to an accumulation of alloxuric bodies in the blood beyond the abilities of the system to eliminate. In the latter instance the elimination has been effectual while physical activity kept all the functions of the body at their best—but the activity ceasing, its stimulating effect on the circulation, the skin, and the digestive tract is withdrawn, and the poisonous substances are less thoroughly removed; while in all probability the man has kept the appetite for food induced by his previous labors, so that the body is over-supplied with nitrogenous matters. In fine, it is necessary that the inheritor or acquirer of gout should remember that he is sentenced for life, and that regular activity is the price of his reprieve.

Treatment of Enteritis by Methylene-blue.—Renon² recommends methylene-blue in the treatment of tuberculous enteritis. Favorable results were obtained by him in 80% of such cases. The drug is usually given in doses of from 0.15 gm. to 0.20 gm. (2 gr. to 3 gr.) daily, either in single dose or in divided doses. It is usually prescribed with lactose, as follows:

Methylene-blue . 0.15 gm. or 0.20 gm. (2 gr. or 3 gr.)
Lactose 0.60 gm. or 0.80 gm. (9 gr. to 12 gr.)

To be made into 4 cachets and taken during the day.

Methylene-blue has also been found useful in other forms of enteritis. Its action is probably due to its inhibitory action on the development of the microbes of secondary infection. [L.F.A.]

Anæsthetic Action of Yohimbin of Spiegel.—Loewy and Muller³ have found that the direct application of yohimbin to peripheral motor and sensory nerves produces complete insensibility; the same effect is produced by its application to mucous membranes. Hirschberg and Loeser have found that the instillation of a few drops of a 0.5% to 1% solution of yohim-

bin in the eye allows of the removal of foreign bodies from the cornea without pain. Loewy and Muller noticed no change in the size of the pupils as a result of its use; it produced, however, ciliary inflammation. [L.F.A.]

Prophylactic Treatment of Migraine.—Combemale¹ considers migraine a manifestation of some constitutional derangement. Prophylactic treatment of simple migraine consists in physical exercise in the open air, the use of food rich in nitrogenous principles, regulation of the functions of the skin and intestines, the avoidance of excessive intellectual work. If the patient suffers from dyspepsia he must be carefully treated; he should abstain from all alcoholic beverages and, if necessary, use large quantities of alkaline mineral waters or laxatives such as cascara sagrada. The gouty diathesis serves as a causative factor and should be treated by the administration of the following:

Lithium salicylate 10 gm. (2½ dr.)
Water 250 gm. (8 oz.)
One dessertspoonful at the principal meal.

Careful attention should be given to the action of the liver and kidneys. [L.F.A.] [Eye-strain must be sought for and corrected. S.S.C.]

Empyroform.—Sklarek,² in experimenting with empyroform, finds that it is very valuable in the treatment of eczema. It calms the itching and stops the oozing without irritating the skin. Empyroform is a condensation product of tar and formol, occurring in the form of a brown, nonhygroscopic powder, of slight odor, insoluble in water, soluble in caustic alkalies, acetone, and especially in chloroform. It is tolerated by patients who are unable to use tar. Sklarek recommends the following formulas:

Empyroform } of each 25 gm. (6 dr.)
Starch }
Vaselin 50 gm. (12½ dr.)

For external use.

Or
Empyroform 15 gm. (4 dr.)
Venise talc } of each 10 gm. (2½ dr.)
Glycerin }
Distilled water 20 gm. (5 dr.)
Alcohol } of each 10 gm. (2½ dr.)
Water }

For external use.

Or
Empyroform 5 gm. to 10 gm. (1 dr. to 2½ dr.)
Chloroform } of each 50 gm.
Tincture of benzoin }

To be used externally.

In other dermatoses, empyroform has not given satisfactory results. [L.F.A.]

Treatment of Acute Gastroenteritis of Infants.—Hutinel³ points out the following main indications in the treatment of acute gastroenteritis of infants: (1) Withdrawal of the source of infection; (2) antiseptics of the intestinal tract; (3) ingestion of water to supply that which is lost. The first indication is met by withdrawing milk entirely, allowing the patient only boiled water in small quantities, frequently repeated. This should be given cold, or even iced, if there is a tendency to vomit; warm or hot if there is a tendency to coldness. In infants less than a year old, after 12 or 15 hours, when the contents of the intestine have been evacuated and the vomiting has stopped, food may again be given cautiously. If the symptoms persist, it may be necessary to wait 24, 36, or even 48 hours. When first returning to a milk diet, it should be given with an equal quantity of water, and gradually increased until the normal amount is again reached. In older children kefir or buttermilk may be allowed. If the vomiting and general symptoms persist for a long time, lavage of the stomach may be performed. Small doses of calomel should be given early in the attack. Intestinal antiseptics may be favored by the use of high enemas of normal salt solution. This should be performed once or twice a day while the stools remain fetid. Hutinel has not obtained favorable results from the administration of salol or other antiseptics. Subcutaneous injection of normal salt

solution has produced good results in extreme cases. The use of hot baths in those cases associated with high fever has produced good results. These may be repeated every 3 hours or 4 hours, and should last about 10 minutes. Pain in the abdomen may be combated by hot applications to the part. [L.F.A.]

FORMULAS, ORIGINAL AND SELECTED.

Snuff for Nasal Affections.—Tissier¹ recommends the following as a basis for snuffs to be used in the treatment of nasal affections:

Powdered boric acid	20.00 (5 dr.)
Salol	1.00 (15 gr.)
Menthol	0.50 (7½ gr.)

This may be used alone or to it may be added various substances; thus, when there are hemorrhagic erosions of the septum 1 gm. to 5 gm. (15 gr. to 75 gr.) of antipyrin, or an equal quantity of pulverized adrenal substance, or of carefully purified alum. In vasomotor rhinitis, Tissier adds a small quantity of cocain (0.10 gm. to 0.20 gm.—¼ gr. to 3 gr.) if no objection exists, and 2 gm. (30 gr.) of quinin sulfate. [Care must be taken not to induce a cocain habit. S.S.C.]

THE PUBLIC SERVICE

Health Reports.—The following cases of smallpox, yellow fever, cholera and plague, have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended February 19, 1904:

Laboratory infection.

Changes in the Medical Corps of the U. S. Army for the week ended February 20, 1904:

FERGUSON, JAMES B., contract surgeon, is relieved from duty at Boise Barracks, Idaho, and will proceed to San Francisco, Cal., and report for duty as transport surgeon on the transport Dix, to relieve Contract Surgeon William H. Tukey, who will proceed to Boise Barracks, Idaho, for duty.

HULL, A. R., contract surgeon, is relieved from duty at Fort Logan and will proceed to his home, New Sharon, Iowa, for annulment of contract.

DEAN, Captain ELMER A., assistant surgeon, is granted leave for ten days, to take effect upon his being relieved from duty at Fort Strong.

SANDS, JOHN R., first class sergeant, will proceed from Fort Baker to San Francisco, Cal., and report for duty on the transport Buford.

SHAW, CHARLES N., first class sergeant, will proceed from Fort McDowell to Fort Baker for duty.

Changes in the Medical Corps of the U. S. Navy for the week ended February 20, 1904:

McCLANAHAN, R. K., assistant surgeon, ordered to the Naval Hospital, New York, N. Y., for treatment—February 12.

NEILSON, J. L., assistant surgeon, detached from the Naval Station, Cavite, P. I., and ordered to the Naval Station, Guam, L. I.—February 18.

WILLIAMS, R. B., passed assistant surgeon, commissioned passed assistant surgeon, with rank of lieutenant, from November 17, 1903—February 16.

BUTLER, C. St. J., assistant surgeon, ordered to the Constellation, with additional duty at the Naval Training Station, Newport, R. I.—February 16.

Changes in the Public Health and Marine-Hospital Service for the week ended February 18, 1904:

STONER, J. B., surgeon, to proceed to Cape Charles quarantine station and assume temporary charge—February 17, 1904.

KORN, W. A., assistant surgeon, granted eighteen days' leave of absence from February 19—February 18, 1904.

WARREN, B. S., assistant surgeon, bureau letter granting assistant surgeon, Warren leave of absence for seven days from February 12, amended to read seven days from February 16—February 16, 1904.

HANRATH, F. R., pharmacist, upon being relieved by pharmacist E. Rogers, to proceed to St. Louis, Mo., and report to medical officer in command for duty and assignment to quarters, relieving pharmacist M. Walerius—February 12, 1904.

WOODS, C. H., pharmacist, relieved from duty at Chicago, Ill., and directed to proceed to Cincinnati, O., and report to medical officer in command for duty and assignment to quarters, relieving pharmacist E. Rogers—February 12, 1904.

WALERIUS, M., pharmacist, upon being relieved by pharmacist F. R. Hanrath, to proceed to Chicago, Ill., and report to medical officer in command for duty and assignment to quarters—February 12, 1904.

ROGERS, E., pharmacist, upon being relieved by pharmacist C. H. Woods, to proceed to Cleveland, O., and report to medical officer in command for duty and assignment to quarters, relieving pharmacist F. R. Hanrath—February 12, 1904.

HERTY, F. J., pharmacist, upon being relieved by Pharmacist B. E. Holsendorf, to proceed to Boston, Mass., and report to medical officer in command for duty and assignment to quarters, relieving Pharmacist L. C. Spangler—February 12, 1904.

SLOUGH, C., pharmacist, relieved from duty at San Francisco Quarantine, and directed to proceed to San Francisco, Cal., and report to medical officer in command for duty and assignment to quarters, relieving Pharmacist M. R. Mason—February 12, 1904.

HOLSENDORF, B. E., pharmacist, relieved from duty at Habana, Cuba, and directed to proceed to San Juan, P. R., and report to medical officer in command for duty and assignment to quarters, relieving Pharmacist F. J. Herty—February 12, 1904.

MASON, M. R., pharmacist, upon being relieved by Pharmacist C. Slough, to proceed to San Francisco Quarantine, and report to medical officer in command for duty and assignment to quarters—February 12, 1904.

SOUTHARD, F. A., pharmacist, granted leave of absence for one day, on account of sickness—February 10, 1904.

SPANGLER, L. C., pharmacist, upon being relieved by Pharmacist F. J. Herty, to proceed to Tampa Bay Quarantine, and report to medical officer in command for duty and assignment to quarters—February 12, 1904.

STIER, C., pharmacist, relieved from duty at Tampa Bay Quarantine, and assigned to duty at Key West, Fla.—February 12, 1904.

BIERMAN, C. H., granted leave of absence for twelve days from February 8—February 15, 1904.

Board Convened.

Board convened to meet at Washington, D. C., April 4, 1904, for the examination of candidates for appointment as assistant surgeon. Detail for the Board: Surgeon D. A. Carmichael, chairman; Surgeon G. M. Gultaras; Passed Assistant Surgeon J. F. Anderson, recorder.

PUBLISHED WEEKLY AT 1321 WALNUT STREET PHILADELPHIA BY THE AMERICAN-MEDICINE PUBLISHING COMPANY

VOL. VII, No. 10.

MARCH 5, 1904.

\$5.00 YEARLY.

A Medical Representative on the Panama Canal Commission is urged by the Committee on Medical Legislation of the American Medical Association. It says that under both of the French administrations at the Isthmus, the engineering problems themselves, to the chagrin of the medical profession of the world, failed of accomplishment largely through the frightful mortality among officers and laborers consequent upon lack of authority on part of medical officers entrusted with the work of sanitation; that the same conditions of insalubrity exist now that existed then, and that, consequently, the sanitary problems are to be recognized as second in importance, if second at all, only to those connected with the engineering department. As a consequence, the Committee, in furtherance of the principle established by the Congress, urges that the technical skill involved in the solution of medical and sanitary problems be likewise invested with highest administrative authority through actual representation in the personnel of the Commission. There can be no question as to the facts stated and none as to the wisdom of the recommendation. The entire undertaking depends upon enlisting the best minds in a thoroughgoing administration of the established scientific principles of sanitation and preventive medicine. Any lapse of attention to this *sine qua non* of success would be enormously expensive in money and lives, and might even prove disastrous. The splendid success of American medical and military methods in Cuba makes it imperative that professional advice and help shall be secured in this great enterprise. Dr. Gorgas, whose appointment is urged, would, as all medical men know, be our most fitting representative on the Committee.

A dispensary for the treatment of pulmonary tuberculosis is to be opened by the Department of Health of New York City. The objects of the clinic are to be: The early recognition and diagnosis of cases of pulmonary tuberculosis, the care of patients applying, the continued observation at their homes of indigent, needy, and ambulatory patients; the removal to a hospital of patients requiring hospital treatment, the provision of a municipal institution to which all tuberculous patients may be referred, the extension and strengthening of the sanitary control of tuberculosis among the poor of the Department of Health, care of patients with

laryngeal tuberculosis. As to the home cases, a special staff of trained nurses will visit the patients at their homes, to see that the instructions given are being observed, that the sanitary surroundings are satisfactory, and that such assistance as is required is afforded. In suitable cases the patient will be referred to the various charitable organizations for food, fuel, ice, etc. Special attention will be paid to the children in the family, and every effort made to prevent their infection. The plan represents a grappling with the practical difficulties of the tuberculosis problem which is most commendable and well worthy of imitation.

Legal Aid Charities.—There are numbers of direct and many indirect ways in which the administration, or rather the maladministration of justice, may cause or result in medical conditions. With the very poor a wrong done them by a hundred forms of illegality may mean the failure to get proper treatment of disease, proper food, etc., upon which health depends. One therefore sympathizes with the movements, too few indeed, which have been made to secure for the deserving poor, legal counsel and help, which is often as needed as the relief for actual disease furnished so liberally by physicians and hospitals. The Legal Aid Society of New York has been in existence for 27 years, and during that time it has handled 146,798 cases. Patterned after this model the Legal Aid Society of Philadelphia was organized in December, 1902, and during the first year of its existence it has taken care of 213 cases, 171 of women, 30 of men, and 12 of infants. The total cost has been less than \$750, and the society appeals for financial assistance. Nonsupport, cruelty, wage claims, rents, fraud, etc., are the chief causes of trouble. The society has been far more careful than the medical profession has been in its charitable work, to avoid pauperizing its applicants, and to prevent any injustice in seeking to do justice.

Public Health and Marriage.—All peoples, except those of the lowest state of development, deemed marriage an institution of the most vital importance toward perpetuation and advancement of human society. At the earliest dawn of civilization religious systems and codes of law sought to regulate by their decrees the social conditions arising from marriage relations in so far

as this state concerned one particular nation or involved mankind in general. Aside from the ethical standpoint the legal aspect received serious consideration—the rights of husband and wife to each other, to their kin, their posterity, as well as to the entire community have been defined and propounded with the closest attention to detail by all tribes, while the physical conditions in their relation to wedlock have never been accorded their proper share of deliberation. To what degree the somatic condition of each spouse influences the matrimonial alliance and vice versa—how far this connubial relationship influences their life and health, that of their offspring, and welfare of the family and community at large—such questions received scant attention from the public authorities. The medical profession, however, has always known the interrelationship between health and marriage, yet it never succeeded in arousing the interest of the public, and in inducing suitable legislation on these points. One could even infer its greater or less indifference in this matter. Recently, two works were published which respectively aim to attract the attention of the educated laity and the legislative bodies, and prove to them the absolute necessity of instituting pertaining laws and regulations. The one book,¹ by a number of authors, is a compilation of essays of intrinsic value upon the relation of ill health and conjugal association. The other, the work of an American author,² dwells upon the influence of the so-called social diseases upon married life and the progeny. Although neither of these works are exhaustive, and the various essays in the German publication are of unequal merit, they cover the ground fairly well, and will undoubtedly arouse the public in general, stimulate to action the clergy, the legislative bodies, and the executive authorities.

Marriage Laws among the Ancients.—The Mosaic Law, which embraces the most detailed hygienic measures, covering all possible phases of life, is remarkably brief in its marriage precepts. It confines itself to rules applying to sexual intercourse to the extent of preventing infection and to the interdiction of incestuous marriages. In the State and religious laws of other ancient peoples, health and disease in their relation to marriage were regarded only in so far as these affected the purpose of marriage. The purpose of marriage has been conceived differently at different times by different nations. At remote periods and among early nations it was the begetting of children—inducing the preservation and increase of the family, tribe, tribal union, or State. From this standpoint possible factors preventing procreation were regarded as inimical to marriage, otherwise no stress was laid upon the physical condition of the parties contemplating wedlock, or that of individuals already thus allied. It was the Spartans who most rationally interpreted the demand of the State by exempting from monogamy and monoandry those whose unions had been issueless, and by exposing sickly and feeble children to perish. The Spartan idea was the “Leitmotiv” of Plato’s essays on “The Ideal State,”

and found expression in Aristotle’s politicophilosophic system. The Spartan usages have at no time been generally accepted, they are entirely antagonistic to modern sentiments and to modern conceptions of humanity and ethics. The ideas of Plato and Aristotle have never been put into practical execution, at least never in their entirety, partly, presumably, because they authorized the central power, the State, to encroach to an unlimited extent upon personal liberty of the citizens, and also since Christianity placed an ethical conception upon marriage.

Individual Health and Marriage.—The influence of married life extends beyond the begetting of healthy offspring. It makes itself felt in other directions. Marriage may be a cause of illness and conducive to the aggravation of certain existing forms of diseases. Disease and physical defects may exert a deteriorating and pernicious influence upon married life, and then again marriage may effect an amelioration in or the cure of morbid conditions. Concerning marriage as a cause of disease, the change in the mode of living generally following matrimonial alliance, the deviation from accustomed conditions, the association with a person of the other sex may give rise to various depressions and manifold disturbances which do not depend upon the sexual intercourse alone, but frequently arise from the inevitable necessity of the greater or less dependence of one spouse upon the other and their adaptation to each other. Naturally, the effects of wedlock are more pronounced in the woman, partly, on account of the greater sensitiveness of her nervous system, and partly because marriage creates a more radical change in the young wife’s mode of living. As to marriage as a source of infection it may become a fertile source for the spreading of ill health by the communication of disease from one person to the other—not only venereal affections but many others, such as tuberculosis, and other communicable diseases are naturally easily transmitted through the close association and joint living of husband and wife. But that marriage is not only a cause of disease, but may also bring about the improvement or even cure of morbid conditions is a fact known to the observer. This is evident when we consider the more settled and usually better regulated mode of living concomitant with the married state.

The Administrative Control of Tuberculosis.—The recent address in Philadelphia, under the auspices of the Phipps Institute, by Dr. Hermann M. Biggs, of the New York Health Department, was a calm and logical presentation of the results obtained by that city in its efforts to check the ravages of tuberculosis. The fall in the tuberculous deathrate, more rapid than in any other large city in the world, and especially true of children under the age of 15, must be in part at least accredited to systematized methods of administrative control. To the honest opponents of such methods of combating the disease we can present no better argument than the published address of Dr. Biggs. One point in the address is worthy of particular attention as answering an objection commonly urged against the registra-

¹ Krankheiten und Ehe. Darstellung der Beziehungen zwischen Gesundheits-Störungen und Ehegemeinschaft. New York: Rebman Company.

² Social Diseases and Marriage: Social Prophylaxis, by Prince A. Morrow. Lea Brothers & Co., 1904.

tion of all cases of tuberculosis. The point in question is that the notification of a case of tuberculosis does not necessarily imply any action on the part of the authorities. If the patient be under the care of a physician, the latter is assumed to employ all necessary precautions to prevent the spread of the disease. To such patients, notification means neither hardship nor annoying publicity. It is with cases without care, or proper care, that the authorities would deal, and this is necessary for the public good. We take it that a large part of the opposition to municipal control of tuberculosis comes from the older members of the profession, who, necessarily, do not appreciate bacteriology, with all that means in the control of disease, as do the younger men, whose advantages in this line have been inestimably greater. We say this advisedly, believing it to be a fact, and absolutely with no intent to cast aspersion upon experienced, able, and honored physicians. It is the duty of the younger men to bring about such change in this sentiment that registration and administrative control of tuberculosis, and all other menacing infectious diseases, shall be made possible. The authorities of any city who seek to establish such conditions should be given the staunch support of the rank and file of the medical fraternity.

Panama.—An excellent report of the sanitary conditions of Panama and the Isthmus is given in Public Health Reports by Dr. Claude C. Pierce, Assistant Surgeon U. S. Public Health and Marine-Hospital Service. From it, one gets a conception of the conditions we shall have to meet when the canal is being built. At the present time the estimated population of Panama is 18,000, composed of 20% Jamaican negroes, 40% native negroes, 5% Chinese, the other 35% being the white natives and foreigners who came to Panama during the French canal work.

Total area of Panama City	acres .	674½
Area of old section	"	250
Total area of streets	"	39
Covered by structures and yards	"	591
Area of squares and parks	"	2½
Space unoccupied by buildings	"	42
Average width of streets	feet .	35

The buildings of the old section of the town are constructed of large bricks, irregularly shaped stones, coral, and a porous stone taken from the beach. Such walls are thick and always damp during the wet season, due to the salt in the material. In the newer or "outside" part of the town the majority of the buildings are wooden shacks. None of these houses is connected with sewers and few have proper privies, consequently the surroundings are extremely filthy and unsanitary. Mosquitoes, all the disease-conveying varieties, are present, and though not highly abundant are more dangerous than if in great numbers, as mosquito nets are not held to be necessary. In January, 1904, the deathrate was 61.33. Leprosy exists in the city of Panama, in the villages along the line of the Panama Railroad to Colon, and in the rural districts. There are 22 known cases in Panama City. There is a collection of shacks, known as a lazaret, on the outskirts of Panama where lepers may go if they choose to and be supported by

charity, but as they are not compelled to be isolated, cases can be found in nearly any part of the city. Beriberi is very common, especially since 1897. During that year, and since then, it could be considered as epidemic along the canal route and in the city of Panama. There are now at least 30 cases in the French hospital in Panama and the city hospital of San Tomas, and many other cases are scattered throughout the town. Not only Chinamen and negroes are affected, but some white men. Smallpox has been epidemic throughout the Republic until recently. Now but few cases exist except in the interior villages. A general free vaccination has bettered the condition. Yellow fever is endemic; only the presence of nonimmunes being necessary for an epidemic, unless the proper precautions are taken. Mosquitoes are prevalent in all the neighboring villages, breeding in the rain-water barrels, in the swamps along the streams, and in ponds. Tuberculosis, dysentery, pernicious malaria, leprosy, elephantiasis, and beriberi are always to be found, and yellow fever and smallpox will occur when favorable clinical material presents itself, unless the proper precautions are taken. Of one of the hospitals, the report says that

"The latrines are very foul, and no provision is made for bathing. Mosquito bars are unheard of, although there are cisterns, wells, and other collections of water in the patio in which mosquitoes breed. There is an old unused gas tank in the yard of this asylum 50 feet in diameter and 15 feet deep that contains some water all the time. Buzzards roost on the trestle around the tank, and several dead vultures can be seen in the reservoir at any time. The tank is absolutely useless and has been for several years a filthy, foul-smelling nuisance. The effect this well-intentioned institution has upon public health cannot be accurately determined, but persons come and go at will, no restrictions being placed upon the inmates, either to enter or leave. Apparently it could well be regarded as a center for distribution of all communicable diseases, as a number of the beneficiaries sleep in the place and beg upon the streets daytimes."

The conclusion of Dr. Pierce is that with a good and abundant water supply and proper sanitation of the city and an efficient quarantine, the health of Panama could be made to compare favorably with the health of coast cities in the Southern States, and the port would no longer be an endemic focus for the distribution of quarantinable diseases.

New Definitions.—Sometime since we cited an illustration taken from "a medical journal" of anatomic ignorance which would have made even a newspaper reporter smile. The answers to correspondents in some of our osteopathic, eddyistic, and other sectarian journals are also shining examples of *lucus a non lucendo*. Those remarkable periodicals devoted to "Physical Culture" and "Health," are also flooding their readers with light from their darkness. A correspondent of "Health" recently sought medical advice from his mentor concerning a permanent enlargement of the pupil of one eye due to a blow. The learned one replied:

The pupil being simply a cylindrical opening, extending from the front to the rear of the eye, the enlargement would appear to be due to a rupture of its walls, and the consequent displacement of the vitreous humour surrounding it.

Dr. Coleman, of Columbus, Ohio, has culled some answers of medical students in certain examinations, which also illustrate the thoroughness of some medical instruction and the value of State Boards of Examiners:

Q.—Bound the inframammary region.

A.—Bound above by the clavicle on either side and neck skin and facia; on the sides by the ribs from the fifth up and below by the diaphragm.

A.—All the parts of the body below the mammary gland and above the symphysis pubis.

A.—The right and left hypochondrium and the epigastrium.

Q.—What are the differential physical signs of ascites, ovarian cyst, and pregnancy?

A.—In ascites the only positive sign that I know is to see some section of a tapeworm pass. Of course, there are other symptoms that may lead you to suspect ascites.

Q.—State fully the physical signs of morbus cœruleus.

A.—A degenerative inflammation somewhere.

A.—Seems like blue disease, so will give emphysema.

A.—I think morbus cœruleus means disease of the cœcum or more nearly the appendix.

Q.—Define normal bronchial respiration, and state where it is heard.

A.—Normal bronchial respiration is a sound heard in the broncho while breathing.

The Antics of an Anti.—Last week's number of our excellent humorous contemporary, *Life*, settles definitely and definitively three great questions in medical science, and for this remarkable service the profession and the race will be forever grateful. The first is the most important one of the existence of germs and the infectiousness of disease. Henceforth all civilized, and even the uncivilized clean, if there are such, may depend upon it that so far as health and the length of human life are concerned, filth, dirt, and carelessness have nothing to do with the generation and dissemination of bacteria or the diseases which are erroneously supposed to be caused by them. In the second place, vaccination is demonstrated to be unnecessary, dangerous, and productive of much suffering. Lastly, operation in appendicitis is "unnecessary." So Dr. T. E. Reed, of Middletown, Ohio, writes to *Life*, and his letter is quoted approvingly. Now, *Life*, as we have said, is a capital humorous paper, but its most humorous humor is that directed against medical science. In the issue thus dashing all our great supposed discoveries and truths, *Life* prints unstinted praise of gin, cocktails, fizzes, rickeys, whisky, ale, cigarets, club cocktails, tobacco, old rye, ale as a tonic, bitters, beers—loss of voice, and all that; but more noteworthy still, a "safe, sure and effective remedy for gout and rheumatism." *Life* probably would say these are not medical things, and hence it is free to advertise them to its trustful readers.

Nurses for Tenements.—A new field of work was opened for the Presbyterian Hospital Training School for Nurses through a gift of \$5,000 by Mrs. W. K. Vanderbilt, on the condition that it be spent to send nurses to attend the sick poor in the city's tenements. Miss Anna C. Maxwell, superintendent of the training school, states that the donation has been made and that "it was to begin the work," indicating that Mrs. Vanderbilt will give largely should the venture prove as successful as she hopes. This first \$5,000 is to be spent during the present year, and there is good authority for stating that Mrs. Vanderbilt intends to spend not less than \$50,000 upon the same work.

BOOK REVIEWS

The New International Encyclopedia. Volume XIII.—Dodd, Mead & Co., New York.

This number extends from New Kensington to Phigalian Marbles. It contains an unusually long list of medical subjects, but many of these are of comparative unimportance and are very briefly treated. Some are unjustifiably abbreviated. Nearly half of the space devoted to obstetrics is occupied by a historic review, while deformities of the pelvis are barely alluded to in this and are completely ignored further on in the 2 pages given to the normal structure. The newborn infant is apparently left to shift for himself, neither his physiologic needs nor pathologic conditions receiving the slightest notice. Four pages are devoted to pedagogy, but pediatrics is not so much as mentioned. Most of the other comparatively long medical articles, while necessarily concentrated, are more comprehensive. Fewer medical men than usual receive notice; the number should have been swelled by the names of Norris, Neumann, Nicolaier, Niemeyer, Nothnagel, Obermeier, Paquelin, Pagenstecher, Parinaud, Parkinson, Pavy, Petit, Peyer, Pfeiffer, and others. Among the medical and relative subjects treated are:

Newton's rings	Oxalic acid
Nickel	Oxaluria
Nicol prism	Oxygen
Nicotine	Oxytocics
Night blindness	Ozena
Nightmare	Ozone
Nitric acid	Pain
Nitrification	Palate
Nitroglycerin	Palpitation
Nitrous ether	Pancreas
Nitrous oxid	Pancreatin
Nosology	Papain
Nostalgia	Papule
Nurses, Training of	Paraldehyde
Nux vomica	Paralysis
Nyctalopia	Paralysis agitans
Obesity	Paranoia
Obstetrics	Parasite
Occupation neuroses	Parasitic diseases
Oedema	Paregoric
Oesophagus, Diseases of	Pareira brava
Official plants	Paresis
Ointment	Patella
Oleic acid	Pathology
Olive oil	Pellagra
Ophthalmia	Pemphigus
Ophthalmoscope	Pennyroyal
Opium	Pepsin
Optic neuritis	Percussion
Organotherapy	Perineum
Ossification	Periostitis
Osteomalacia	Peritonitis
Osteopathy	Pestilence
Otalgia	Petechia
Otitis media	Pharmacopeia
Otorrhea	Pharyngitis
Ovary	Phenacetin

The following are without treatment or cross references:

Newborn infant	Orbit, Diseases of
Nictitation	Ox-gall, Medical uses
Night sweats	Pack
Nocturnal emissions	Paper, Medicated
Nocturnal enuresis	Paraffin (surgical uses)
Nose, Diseases, Deformities, etc.	Paramyoclonus
Nystagmus	Paronychia
Onomatomania	Pathologic technic
Ophthalmometer	Pediculosis
Opisthotonus	Pelvis, Deformities of
Optic atrophy	Penis, Diseases of

A Textbook of Legal Medicine and Toxicology.—Edited by FREDERICK PETERSON and WALTER HAINES. W. B. Saunders & Co., 1904. Volume II.

Volume I of this book appeared during the summer of 1903 and was reviewed in the issue of this journal of July 25, 1903. Volume II, just issued, includes a continuation of Part I of Volume I, treating of Legal Medicine, and a Digest of the Statutes of all the States and Territories, and of the District of Columbia, relating to the Commitment, Care, and Custody of the Insane, to which subjects 296 pages are devoted. The remaining part of the volume is devoted to Toxicology. The

various subjects under the heading Legal Medicine are described in a clear and concise manner. The latest opinions on the subjects are given. The chapter on "Expert Evidence" explains the duties and privileges of experts, and contains suggestions concerning methods of obtaining information from medical experts and other witnesses which should be valuable to the examining attorneys. An especially important topic, which is treated somewhat in detail, is the medicolegal aspects of the untoward effects of the röntgen rays. The part devoted to Toxicology covers the entire scope of the subject and, among other good things, possesses the merit of including only those methods which experience has shown to be reliable. It is a book which must be of great value to members of the medical profession, to toxicologists, and to attorneys interested in forensic medicine.

Diseases of the Eye.—By L. WEBSTER FOX, A.M., M.D. D. Appleton & Co., New York.

This volume is well illustrated, in many instances with original photographs. A pleasing feature from a literary standpoint is the concise historic sketch that is often incorporated in the discussion of the more important methods of diagnosis and treatment. There is an excellent chapter on Ocular Affections in General Diseases, and the sections on the Pupil in Health and Disease and Injuries of the Eye in Parturition will be appreciated by the general practitioner. A convenient glossary and an extensive index are appended. The printer has not kept pace with the author, for the book bears marks of hurried proofreading, and faults in style of type, alignment, etc., are too frequent. The use of the word "vision," instead of "vitreous" on page 327 affords an example of the confusion of sense that a proofreader's slip may cause. As a rule proper names are carefully spelled, but Darrier appears for Darier on page 116, Meyers for Myers on page 120, Thompson for Thomson on page 298, and Levi for Levis on page 546. The noticeable lack of system and uniformity in terminology and the somewhat questionable Latin in which some of the formulas are given, suggest the wisdom of the more general use of plain English terms throughout the text.

BOOKS RECEIVED.

[Prompt acknowledgment of books received will be made in this column, and from time to time critical reviews will be made of those of interest to our readers.]

The Artificial Naueim Bath: Its Uses, Methods, and Results. The Naueim Bath, New York City.

Eighteenth Annual Report of the State Board of Health, and Vital Statistics of the Commonwealth of Pennsylvania. Transmitted to the Governor, November 28, 1902. Wm. Stanley Ray, State Printer of Pennsylvania, 1903.

International Clinics, Vol. IV, Thirteenth Series, 1904: A Quarterly of Illustrated Clinical Lectures and Especially Prepared Original Articles on Treatment, Medicine, Surgery, Neurology, Pediatrics, Obstetrics, Gynecology, Orthopedics, Pathology, Dermatology, Ophthalmology, Otology, Rhinology, Laryngology, Hygiene, and other topics of interest to students and practitioners by leading members of the medical profession throughout the world.—Edited by A. O. J. KELLY, A.M., M.D., Philadelphia, U. S. A. With the collaboration of William Osler, M.D.; John H. Musser, M.D.; Joseph Stewart, M.D.; J. B. Murphy, M.D.; A. McPhedran, M.D.; Thomas M. Rotch, M.D.; John G. Clark, M.D.; James J. Walsh, M.D.; J. W. Ballantyne, M.D.; John Harold, M.D.; Edmund Landolt, M.D.; Richard Kretz, M.D.; J. B. Lippincott Company, Philadelphia, 1904. Price, cloth, \$2.00 net.

Transactions of the American Dermatological Association, at its Twenty-seventh Meeting held in Washington, D. C., May 12, 13, 14, 1903, in connection with the sixth triennial session of the Congress of American Physicians and Surgeons. Official report of the proceedings by CHARLES J. WHITE, M.D., Secretary. The Grafton Press, New York.

Diseases of the Nervous System: A Textbook for Students and Practitioners of Medicine.—By H. OPPENHEIM, M.D., Professor at the University of Berlin. Translated and edited by EDWARD E. MAYER, A.M., M.D., Pittsburg, Pa. Second American edition, revised and enlarged. With 318 illustrations. Price, cloth, \$5.00 net. J. B. Lippincott Company, Philadelphia, 1904.

A Handbook of the Prevention of Tuberculosis. Published by the Charity Organization Society, New York City, 1903.

System of Physiologic Therapeutics: A Practical Exposition of the Methods Other than Drug-giving, useful for the Prevention of Diseases and in the Treatment of the Sick.—Edited by SOLOMON SOLIS COHEN, A.M., M.D., Senior Assistant Professor of Clinical Medicine in Jefferson Medical College; Physician to the Jefferson Medical College Hospital, and to the Philadelphia, Jewish, and Rush Hospitals, etc. Vol. viii, Rest, Mental Therapeutics, Suggestion, by FRANCIS X. DER-CUM, M.D., Ph.D., Professor of Nervous and Mental Diseases in the Jefferson Medical College of Philadelphia; Neurologist to the Philadelphia Hospital; Consulting Physician to the Asylum for the Chronic Insane at Wernersville; Consulting Neurologist to the St. Agnes Hospital; Consulting Neurologist to the Jewish Hospital, etc. P. Blakiston's Son & Co., Philadelphia, 1903.

AMERICAN NEWS AND NOTES.

GENERAL.

The Society for Psychical Research.—At the recent meeting of the Society for Psychical Research, it was announced that the sum of \$30,000 had been collected for a scholarship, which it was hoped would be increased to \$40,000. The English society now numbers 832 members, and the American Society 530 members.

Diphtheria on War Ship.—News from San Juan, P. R., under date of February 25 says: Five cases of diphtheria are reported on board the United States Ship Monongahela. The crew and officers have gone into camp at the naval station until the ship shall have been fumigated. The sick men are not believed to be in danger.

Portion of Needle in Her Body for 16 Years.—According to reports 16 years ago a woman of Camden, N. J., stepped on a needle that penetrated one of her heels. In removing the needle it broke in half, and efforts of physicians to locate the other half were of no avail. To her surprise recently she found the long-lost portion of the needle had protruded from the skin above the knee. It was removed with difficulty.

The National Congress of Mothers will be held this year in Chicago, May 11 to 14. The national boy problem, moral education, uniform marriage and divorce laws, education for the art of life, industrial education a factor in civic betterment, child labor conditions, the probation method, the dependent and delinquent children, literature for mothers and children, mothers' mistakes, and domestic science are subjects that will be included on the program.

Athletic and Physical Development of the Army.—General Frederick D. Grant believes the soldiers in the department of the lakes should be athletes, and has prepared a program for the systematic instruction of the men at Fort Sheridan. There will be baseball, handball, football, and track teams. In July there will be competitions and prizes are to be awarded. An order was issued requiring that at least 2 hours a week be devoted to gymnastics and calisthenics.

Miscellaneous.—NEW YORK: A grant of \$500 was given this year by the Rockefeller Institute of Medical Research to Dr. A. S. Warthin, professor of pathology in the University of Michigan, for his researches on the etiology of the anemias. The grant has been used for the establishment of a fellowship in pathology, to which Mr. H. Woltmann has been appointed. —To AID DR. REMICK: "Reader, M.D.," sends \$2 for fund to aid Dr. Remick, "an unfortunate colleague," mentioned in recent issues.

Nurses for Japan and Korea.—The 10 nurses who are to be sent to Korea by the Philadelphia branch of the society to aid Japanese and Russian soldiers during the war will leave Philadelphia on March 17 for the seat of action. It has been definitely decided that five will go from Philadelphia, two from Boston, and three from Washington. They will arrive in San Francisco on March 22, and start on the voyage to Yokohama the following day on the steamer Siberia. Upon their arrival in Japan the nurses will be at the direction of the Japanese Red Cross Society, but in the field they will act entirely neutral, going wherever needed.

Adulterated Tomato Catsup.—From our analyses and comparison of our results with those obtained by other analysts it would seem that all the tomato catsups on the market are adulterated, either by coloring matter, or preservatives, or both. Such practice seems unnecessary and injurious to the trade, in view of the fact that we have recently opened bottles of catsup put up some 12 years ago and found them in perfect condition. The addition of coloring matter to catsups gives the goods a brighter, though unnatural color, and allows the use of green and inferior stock. The catsup manufacturer has evidently the idea that he must add some color, and he frequently does so without regard for hue or shade. A sample recently examined was yellowish and proved to be colored with annatto. The statement of a local manufacturer that in preparing his catsups he used an ounce of salicylate of soda to every 8 bottles shows the extent to which the drugging of these products is carried.—[N. H. Sanitary Bulletin.]

Railroad Casualties.—According to a bulletin issued February 10 by the Interstate Commerce Commission, showing the railroad accidents in the United States during July, August, and September, 1903, 60 passengers and 220 employees were killed and 1,663 passengers and 1,914 employees injured, making in all 280 persons killed and 3,582 injured in train accidents. Other accidents to passengers and employees, not the result of train accidents, make the total number of casualties 15,187; 109 passengers and 916 employees killed, and 2,688 passengers and 11,474 employees injured. The total number of persons killed during the quarter shows an increase of 181, and the number killed in train accidents 280, as against 230 for the preceding quarter, shows an increase of 50. Seventy employees were

killed in coupling and uncoupling cars, an increase of 8 over the number of fatalities for this cause in the preceding quarter. The total number of collisions and derailments was 3,603 (1,765 collisions and 1,298 derailments), of which 251 collisions and 251 derailments affected passenger trains.

Pure Food Bill in the Senate.—As amended and revised the bill which is now before the United States Senate and which probably will be passed reads as follows: "To investigate the adulteration of foods, drugs and liquors when deemed by the Secretary of Agriculture advisable, and the Secretary of Agriculture, whenever he has reason to believe that articles are being imported from foreign countries which are dangerous to the health of the people of the United States, shall make a request upon the Secretary of the Treasury for samples from original packages of such articles for inspection and analysis, and the Secretary of the Treasury is hereby authorized to open such original packages and deliver specimens to the Secretary of Agriculture for the purpose mentioned, giving notice to the owner or consignee of such articles, who may be present and have the right to introduce testimony, and the Secretary of the Treasury shall refuse delivery to the consignee of any such goods which the Secretary of Agriculture reports to him have been inspected and analyzed and found to be dangerous to health or falsely labeled or branded.

NEW YORK.

Law Does not Require that Vaccination Shall Take, in New York.—Attorney-General Cunnene holds that the law requiring public school children to be vaccinated has been obeyed when a child has been inoculated with vaccine virus, even though there is no outward sign by swelling or soreness that the virus has had the desired result, and though a number of attempts upon the same individual do not take.

War on Spitting.—Health Commissioner Darlington has announced that no further leniency is to be shown toward violators of the provision of the Sanitary Code that makes spitting in public a misdemeanor. Officers of the Health Squad have been ordered to make summary arrests in all cases. The streets and sidewalks, railroad platforms, and all other public platforms are said to be in a filthy condition, and the Health official now gives formal notice through the press that there is to be no more leniency toward offenders.

Surgical Outfit for Each Hook and Ladder Truck.—Twenty-five leather surgical cases, part of a similar equipment which is to be extended throughout the Fire Department, were distributed recently among the hook and ladder companies of Manhattan and Brooklyn boroughs, by order of Fire Commissioner Hayes. The idea of thus equipping the firemen is one conceived by Chief Croker some time ago, but only now put into operation. In time every fire company in the greater city will have one of the cases as part of its outfit.

New York Hampered in Its Fight against Tuberculosis.—The annual report of the State Charities Aid Association to the State Board of Charities has recently been made public. It says in part: One of the most disastrous measures passed by the Legislature and signed by Governor Odell was that which forbids the establishment of any hospital or camp for the treatment of patients suffering from pulmonary tuberculosis in any town without the consent of the town's governing board and of the Board of Supervisors of the county in which the town is. The effect of this law is to make it impossible for any city in the State, or any fraternal order, charitable society or philanthropic individual to establish a hospital, camp or other establishment for the treatment of the tuberculous outside the city limits, except under conditions which are practically prohibitive. The report says that in the opinion of the association the country districts were sufficiently protected by the laws then existing, which forbade the establishment of any institutions for the tuberculous in the State without the approval of the State Board of Health and which laid down other restrictions.

PHILADELPHIA, PENNSYLVANIA, ETC.

The New Municipal Hospital for Infectious Diseases.—Although the new smallpox hospital is nearly ready for occupancy, there is no likelihood that the old institution will be soon vacated. Funds for the completion of the hospital will come from the new \$16,000,000 loan, which contains an item of \$1,000,000 for the work. What is needed now to complete the hospital is a heat, light, and power plant, for which plans will soon be prepared.

Typhoid and Pneumonia Still Prevalent.—There were 148 new cases of typhoid fever reported to the Bureau of Health for the week ended February 27, the greatest number for any one week in the past 10 months. The reports of the physicians show that disease prevails in every ward of the city with the exception of the Eleventh, Sixteenth, and Twenty-first. Last week was also a record breaker in typhoid fever cases, the number reaching 142. There was a marked increase in the city's mortality which reached a total of 693, of which 120 alone were due to pneumonia. This is only 5 less than last week's record, which was unusually heavy.

Crusade of Vaccination Closed.—The vaccine corps attached to the Department of Health of Philadelphia, which was legislated out of office on December 31 last, and was succeeded by the appointment of new medical inspectors, performed vaccinations on 207,000 persons in Philadelphia in the period between July 10, when active work was begun, until December 31 last. Of this number reports to the health officials indicate that 156,000, or 75%, of the vaccinations were successful.

Wood Alcohol in Whisky.—The discovery that wood alcohol is used to a large extent in this city to adulterate whisky has been made by Dr. Warren, State Dairy and Food Commissioner. Prosecutions against those trafficking in this liquor have already been begun in the country districts, and the first steps in this direction against dealers selling it have been taken. Attorneys of the department have been instructed to proceed vigorously against dealers here whose goods show, according to chemists, that wood alcohol and other forbidden ingredients have been used. Informations have been filed against wholesale and retail liquor dealers, and warrants have been taken out. Dr. Warren says that the use of wood alcohol in liquor has been proved most dangerous to health. It may not only cause total blindness, but death.

SOUTHERN STATES.

Medical Branch of the U. S. Army.—A bill has been introduced in Congress for the reorganization and promotion of the efficiency of the medical branch of the army. The bill is indorsed by Secretary of War Taft, Surgeon-General O'Reilly, and the General Staff of the Army, and in principle by former Secretary of War Root, because it will abandon to a large extent the present system of contract surgeons. As reorganized, the medical branch of the army will consist of a surgeon-general, with the rank of brigadier-general; a medical corps, a medical reserve corps, a hospital corps, and a corps of nurses and dental surgeons. The medical corps will be made up of 12 colonels, 18 lieutenant-colonels, 110 majors, and 300 captains and lieutenants, all ranking like similar officers in the cavalry branch of the service. The bill provides that the present officers of the medical branch of the army shall be recommissioned in relative order of seniority, the assistant surgeon-generals as colonels, the deputy surgeon-generals as lieutenant-colonels, the surgeons as majors, the assistant surgeons whose commissions date prior to last Christmas to be captains, and other assistant surgeons to be first lieutenants.

WESTERN STATES.

Insane Asylum Burned.—Information from Racine, Wis., under date of February 20, states that all of the 133 patients in the Racine County Insane Asylum, which burned February 19, were rescued in some cases with the greatest difficulty. The loss aggregates \$115,000, with insurance of \$35,000.

Race Suicide in Portions of Wisconsin.—Here are some of the figures made public by Mr. Torrey, the register of deeds in Kenosha county, which, he declares, are characteristic of the entire county: The town of Bristol with 2,000 population, had but 1 birth in 1903. Wheatland, with 1,000 population, had but 1 child born in a year. Brighton, populated by sturdy Germans, reported but 4 births. At one time during the year there were 17 spinsters living in a single Kenosha street. This dearth of children is among the middle, not the wealthy class. The rich families, of which Kenosha has more than any other city of its size in the State, are all large, some numbering 10 children. In Bristol, figures show that women outnumber the men about 5 to 3. In Kenosha, the number of factory girls brings the proportion to about the same figures.

Chicago Secures Antitoxin.—The Bulletin of the Chicago Health Department, for the week ended February 20, says: As a result of the commissioner's recent eastern trip in search of diphtheria antitoxin at reasonable prices the department is enabled to announce the immediate reestablishment of the antitoxin stations throughout the city. Thanks to the public spirit of the commissioner and president of the New York City Board of Health, Dr. Thomas Darlington—the first installment of 500 vials of the New York product was received at the close of the week, and triweekly installments have been arranged for so as to supply a sufficient number of stations, so located that no physician need send further than half a mile for the remedy. The prices for the present will be those of the New York Board, viz., 75 cents for 1,000 units, \$1.25 for 2,000 units, and \$2.25 for 3,000 units.

Honor Dr. Andrews' Memory.—As a tribute to the memory of Dr. Edmund Andrews, of Chicago, a notice of whose death has previously appeared in these columns, memorial services were recently held in his home city. The meeting was arranged under the joint auspices of the Chicago Medical Society, Chicago Surgical Society, the Illinois and Michigan State Medical Societies, American Medical Association, Grand Army of the Republic, Academy of Sciences, and the Northwestern, Chicago, and Illinois Universities, with the work of all of which Dr. Andrews had been identified. The principal

address was made by Dr. F. W. Gunsaulus, who eulogized Dr. Andrews' character as a man, as well as his greatness as a physician. Other speakers were Dr. Victor C. Vaughan, of the University of Michigan; President James, of Northwestern University; Professor J. C. Grant, of the Harvard School; Dr. J. H. Hollister, of the Chicago Medical College; H. W. Dudley, of the Grand Army of the Republic; and Dr. N. S. Davis, of the Academy of Sciences.

Antitoxins and Diphtheria.—The Bulletin of Chicago's Health Department, for the week ended February 13, makes a comparison in the mortality from diphtheria between the 2 periods from 1888 to 1895 and from 1896 to 1903. During the former period antitoxin was not used by the Health Department in combating diphtheria, and in the latter period it has been used. According to this the reduction in actual number of deaths was 5,400, or 47%. Before using, the deathrate per 1,000 was 12.45, while during the late period it was 4.55. Decrease of diphtheria deaths, 63.4%. Between October 5, 1895—date of first case treated—and December 31, 1903, the Antitoxin administrators of the Department treated 7,435 cases of bacterially-verified diphtheria, of which number 479 died—a mortality rate of 6.44%. The average mortality without antitoxin still remains about 35%. That the value of antitoxin depends upon its early administration is shown by the following: Of the total 7,435 cases, 585 were treated on the first day of the disease, with 2 deaths—mortality rate, 0.34%. Of 1,913 treated on the second day, 28 died—mortality rate, 1.46%. Of 2,624 treated on the third day, 85 died—mortality rate, 3.24%. Of 1,374 treated on the fourth day, 148 died—mortality rate, 10.8%. Of 936 first treated later than the fourth day, 216 died—mortality rate, 23.1%.

FOREIGN NEWS AND NOTES

GENERAL.

Has He Cured Cancer?—News from Paris under date of February 22 states that Dr. Doyen, has read a paper before the Academy of Medicine on a new method of treating cancer by injecting serum prepared from *Micrococcus neoformans*, a microbe peculiar to cancerous tumors. Of 126 cases treated in 2 years, 58 did not show favorable results, 47 improved in varying degrees, and 21 now do not show any trace of cancer and are regarded as cured.

Fighting to Prevent Yellow Fever in Mexico.—Information from the City of Mexico, under date of February 27, says that the Mexican Government has decided to spend \$7,000,000 during the present year to prevent a recurrence of yellow fever within its borders. Important sanitary work is now under way at Vera Cruz, which is regarded as a distributing point for the infection. The comprehensive plan for suppressing and preventing yellow fever in cities and towns of northwestern Mexico has been devised by Mr. Lyega, Chairman of the Superior Board of Health. The plan is to follow the course the board took last summer and take rapid action should the fever again show itself. Mosquitos will be thoroughly destroyed. The board proposes to work in entire harmony with the health authorities of the United States and the State of Texas. The remarkable exemption of the City of Mexico from typhoid fever this year is an indication of what can be done by sanitation.

A Fund to Encourage the Study of Bacteria.—At the ordinary quarterly *comitia* of the London Royal College of Physicians, held on January 30, the president, Sir William Church, announced that Dr. Horace Dobell, of Dorset, had presented a sum of £500 in cumulative consols to the college for the promotion of original research into the ultimate origin, evolution and life history of bacilli and other pathogenic microorganisms. The conditions are, that the president and censors of the college shall select a lecturer once in every 2 years, who shall give a record of original researches on the above subject, made by himself and others, and that he shall receive a fee of £50 for so doing. These lectures are to be continued biennially, as long as a sufficient amount of the £500 and its accumulated interest remains. The first lecture will be delivered during the year 1904.—[*Science*.]

Crusade against Rats.—Dr. Adrien Loir, a Paris professor of hygiene, says: "The president of the French republic has just issued a decree calling for the wholesale destruction of rats on shipboard. The science of Pasteur has shown us that the principal propagator of the plague is the rat. Those rodents, as is well known, go on shipboard in the remote countries where the epidemic is constantly raging, reach our shores, and thus spread the germs among us. The most effective means of protecting ourselves against this evil is therefore to wage pitiless war upon rats." In commenting upon this, a correspondent makes the statement that before the plague attacks men it invariably exterminates a great number of rats. The Hindus and the Chinese know that the plague is approaching when the rats leave their dwelling places by hundreds and flee from the

district, as they do when they see a great many of their fellow-parasites killed off. They instinctively fly from the danger, and they leave the stricken region to return thither only after a long period. This is how they spread epidemics, and their destruction is therefore a prime desideratum.

Physical Decline in England.—From statistics presented to the House of Commons by the Home Secretary there has been a steady annual increase in the last 10 years in the police court cases of drunkenness in England and Wales. Between 1892 and 1896 the cases numbered 583.47 per 100,000 population; between 1897 and 1901, 642.87; in 1901, 644.84; and in 1902, 666.16. The actual number of cases has grown from 175,627 in 1892 to 219,908 in 1902. This is a very unfortunate showing, and is all the more significant when taken in connection with the returns of recruiting officers. An army officer quoted in the *London Express* says: "In the last 20 years stature and chest have so dwindled that if we attempted to enlist on the standard of the 80s we should reject 70% of the men offering." Since April, 1899, the number of men rejected as unfit was 113,000 out of 365,000 candidates, and in addition 10,000 recruits were invalidated within 2 years of enlistment. Every third man is thus a "defective." This is a bad showing for the United Kingdom, and a royal commission is at work to investigate the cause of this condition of the national physique.—[*Philadelphia Press*.]

OBITUARIES.

William Rankin, Jr. at his home in Newark, February 26, aged 56; a graduate of Rutgers College in 1868 and four years later from the College of Physicians and Surgeons in New York. He studied extensively abroad and at the time of his death was secretary of the Newark Eye and Ear Infirmary and one of the operative surgeons connected with the institution.

David D. Toal, at his home in New York, February 26, aged 66. Being born in Ireland he was brought to this country by his parents when he was but two years of age. He educated himself by working in shops and was graduated from the University Medical College in 1867. He was extensively known both politically and socially on the lower East Side.

John R. Hinkson, at his home in Blissville, Long Island City, aged 48; a graduate of Bellevue Hospital Medical College in 1889, and at one time a professor of surgery in that institution. Had lived in Blissville about fifteen years. Was a member of the Queens-Nassau Medical Society, and was noted for his generosity and kindness to the poor.

Frederick G. Winter, at Kingfield, Me., February 11, aged 46; a graduate of the Long Island College Hospital, Brooklyn, in 1882. He was formerly president of the Brooklyn Medical Society and surgeon to the Twenty-eighth Infantry, N. G., N. Y.

Ephraim P. Russell, at the Walter Sanitarium, Evansville, Ind., February 16, following a surgical operation, aged 61; a graduate of Jefferson Medical College and member of the Clinton County Medical Society.

Charles Elliott Denig, at his home in Columbus, Ohio, February 9, aged 78; a graduate of the Stirling Medical College, Columbus, in 1850, and a surgeon of the United States army during the Civil war.

Frank A. Box, of Pulaski, N. Y., from pneumonia, at the Oswego Hospital, February 11, aged 38; a graduate of the State University of Iowa and the College of Homeopathic Medicine, Iowa City, in 1890.

McDuffie Blanchard, at his home in Columbus, Ga., February 12, from pneumonia, aged 68; a graduate of the University of Nashville in 1857, and a surgeon in the Confederate army during the Civil war.

Maximilian G. Raefle, at his home in New York City, February 13, from apoplexy, aged 67; a graduate of Humboldt Medical College, St. Louis, in 1861; a surgeon in the U. S. N. during the Civil war.

James M. Laird, at Sheltering Arms Hospital, Paint Creek, W. Va., February 15, aged 51. He was a wellknown practitioner of the Kanawha and New River Valleys, W. Va.

Frank LeRoy Tetamore, was drowned with a party of eight officers near Manila, P. I., February 10. He was captain and active assistant surgeon of Volunteers, U. S. A.

Wm. E. Woodbridge, at his home in Washington, February 23, aged 80. He was the inventor of the rifle gun and an expert in ordnance and explosives.

Sereno E. D. Bumstead, at his home in South Framingham, Mass., February 14, aged 81; a graduate of Harvard Medical School in 1844.

Charles E. Cook, at his home in Huntley, Ill., February 13, from double pneumonia, aged 51; a graduate of Chicago Medical College in 1880.

John W. Thompson, of Hillsboro, Ark., was shot and killed February 12; a graduate of the University of Arkansas, Little Rock, in 1877.

Albert Trenchard, at his home in Glassboro, N. J., February 11, aged 60; a graduate of Jefferson Medical College in 1870.

Joseph R. Askew, at his home in Jacksonville, Ill., February 11; a graduate of the University of Pennsylvania in 1841.

CLINICAL NOTES AND CORRESPONDENCE

[Communications are invited for this Department. The Editor is not responsible for the views advanced by any contributor.]

THE HISTORY OF THE TREATMENT OF GONORRHEA WITH SPECIAL REFERENCE TO THE LINES ALONG WHICH IMPROVEMENTS MAY BE ANTICIPATED.

BY

G. S. PETERKIN, M.D.,

of Seattle, Wash.

In studying the history of the treatment of this disease, the student is immediately impressed with the fact that the treatment of gonorrhea employed at various periods depended upon notions that the medical men of the day entertained as to its nature and causes. The disease has existed from time immemorial, as is clearly shown by the writings of Moses, 14 centuries before Christ. Nevertheless, though it may seem strange, the methods employed at all times, irrespective of the theories held as to the causes of the disease, have varied so slightly that they may be conveniently classified under one of the 3 well-known modern divisions of treatment: The expectant treatment, rest, diet; the modified expectant treatment, rest, diet, drugs internally; the local or injectional.

Considered from an evolutionary standpoint, the primeval mode of treatment was undoubtedly the expectant. And the universal treatment of today, the injectional, is itself as antiquated as authentic history, for in the most ancient medical writings existing, the Papyrus Ebers (1,600 years B. C.), we find the injection of different vegetable extracts recommended for discharges of the genital organs. The Greeks and Romans used injections. They borrowed a greater part of their knowledge from the Egyptians, and sweet milk and honey was injected into the urethra, not only to propitiate Venus, but at the same time to cleanse the canal; with the result that each, infidel and believer, worked with equal zeal.

The sciences of the middle ages built their superstructure upon Egyptian learning also. An investigation of the authors of this epoch shows that the treatment of gonorrhea still retained its primitive form until about 1850 A.D. The slow progress in improving the treatment of this disease during these centuries may be accounted for on the grounds that learning was confined to a very limited class, the nobility and the clergy, and medicine, for this reason and for opportunities it presented for benevolence and charity, was practised as an art and science, mainly by the latter class. Environments, the lack of educational opportunities, class prejudices, etc., prevented others from entering its confines, except in a desultory manner that placed them in the position of the mountebank or quack of today. Moreover, during these times and by all classes, venereal diseases were regarded as heaven's judgment for a voluntary immoral act, and as loathsome diseases, contaminating even those who mentioned them. A sufferer was receiving only his just dues, was, in fact, atoning for his misdeeds. With such sentiments, and with the power to act in the hands of religious bodies whose creeds bordered upon fanaticism rather than humanitarianism, naturally advancement could not be expected.

Though possible to classify the forms of treatment, it is impossible to consign any one of them to a definite period. In the history of venereal diseases it is the technic rather than the principles of treatment that have been modified. For example take injections, the principle of using a syringe has been constant as has been shown, and the modifications in treatment have followed along the lines of medication, evolving from the stage of sweet milk and honey, previously mentioned, through innumerable numbers to the modern antiseptics and astringents of today.

The notions entertained as to the causes and nature of the disease, however, permit of a division of the history of venereal diseases into 3 natural epochs: (1) The religiophilosophic and metaphysic period from the year 1500 B.C. to about 1700,

A.D.; (2) the clinical, from 1700 to 1879; (3) the microbic, from 1879 to date, 1904.

As to the first period, enough has already been said as to the general belief that an omnipotent power was the cause of the disease, yet it may be of interest to sketch some of the ideas held by individual authorities. The opinion of Hippocrates, the father of physic; Celsus, Galen, and other ancient writers, can be readily dismissed, for though they mention various affections of the generative organs, they are not stated to have followed sexual intercourse.

In the thirteenth century the contagion was attributed to foul women, and was supposed to originate in hot humors which found their way out of the body through the womb. Thus the pure expectant treatment again came in vogue, and the discharge, supposed to consist of laudable pus, was not checked, as it chased the bad humors from the body. A clever idea at times put into practice today, I believe?

In the fifteenth century the theory of astrologic influences was held even by the best educated physicians of the times, though it was union that caused the disease, it was union of the gods, Venus with Mars, or Jupiter with Venus. And though the chivalry of the middle ages has passed, yet the human characteristic of blaming someone else, if not the gods, still exists. Later, more special causes were sought for, and it was attributed to leprosy, ulcers of the womb, use of lime in bread, to wells poisoned by the Neapolitan. (The renowned Fallopius was an ardent advocate of this latter cause.)

In the seventeenth century, even Van Helmont believed the disease sprung from unnatural connection between man and horse. Many more hypotheses as vague and fantastic as these could be given, but being the principal ones, I shall desist and pass to the second, or clinical period, and to the authorities and makers of history in this branch of medicine. I speak of masters—Astruc, Hunter, and Ricord. Astruc, physician to Louis XV, in 1736, wrote the first methodic treatise on venereal diseases, claiming that venereal diseases were brought to Europe by the followers of Columbus. His work was divided into 2 parts: the first described the first stage or local venereal disease and included: (1) Virulent gonorrhea; (2) venereal bubos; (3) chancres; (4) verrucas and condylomas.

In the second or systemic stage, he classified the constitutional symptoms of syphilis anatomically under 9 separate headings. It must be here recalled to mind, before proceeding further, that even during this period clinically, gonorrhea, chancroids, chancres and syphilis were considered one and the same disease until Benjamin Bell in 1782 brought forward his experiments and reasons for separating gonorrhea from syphilis and chancre. The great Hunter, like Astruc, admitted the existence of a venereal virus, but maintained that the one virus caused all the venereal diseases and affected the system in two ways, primarily or locally, secondarily or constitutionally. That when the virus came in contact with the mucous membrane, gonorrhea resulted; on the contrary, when it came in contact with the skin, chancres.

From Astruc's and Hunter's time the genitourinary surgeons were practically divided into 2 great camps. The "virulists," among whom were Diday, Rollet and Martin; who were so by a sort of nosologic instinct, by a conviction that could not be proved. But a greater number of the medical men shared the opinion of Brüssais on this point and believed it quite a local inflammatory disease. They were the "antivirulists" or phlogogenists, because of the hypothesis (maintained by Ricord) of a catarrh produced by the contact of two organisms, both equally pure and created by the ardor of embraces.

The germ theory, which began to develop about 1820, and reached its full development in 1850, had no material influence on venereal diseases until 1879, when Neisser discovered the specific germ of gonorrhea—the gonococcus. With the discovery of this germ, there has developed a fallacy that again threatens to plunge us into a period of inactivity. This is that a germ is not subject to the laws of evolution and has a "specific consistency" of infection. In other words, the belief that to cure a disease all we have to do is first discover the specific germ, then the remedy that will kill the germ and—the disease will vanish.

We forget that the gonococcus is an organic being and subject to the same evolutionary laws as man. Therefore in adapting itself to its environments, it is capable of not only having its type changed, but also of having its properties modified. This practical fact, that a germ may generate new and virulent properties, is one worthy of being remembered.

Today the treatment of gonorrhea stands almost as it did 20 centuries ago; expectant, modified expectant and injective, with the addition of this one great step, the discovery of the specific germ. Why has not this discovery caused greater improvement in the treatment of this disease than now exists? For one simple reason, we have not learned the lesson history teaches, that a fact taken in the abstract is often a stumbling block to progress, but are attempting to improve the treatment along one and the same line as our ancestors did before us. By changing or improving the drug used. For this today, is the popular dictum in treatment. Try one antiseptic drug; administer it hot, or administer it cold. Make the dose large or make it small. Let it remain a long time or let it remain a short time, but, if you do not succeed, try another.

I am not decrying this means of attaining a cure, for it has netted some very good results, one of which is the albuminated salts of silver. But is that the only line along which we should work? Is it rational and scientific to believe so? Let us for a moment review briefly all the lines along which improvements may be anticipated.

1. Biochemic research and observation along evolutionary lines, will enable us to control the life of the microorganism and thus its infectious properties, and likewise comprehend the factors that decrease the susceptibility of the human body for the gonococcus and increase its resistance to it.

2. By construction of a syringe with due regard to the anatomy and physiology of the parts, one that can be used by the patient himself, that can be used both for interior and posterior injections, that can be sterilized, and yet, be so regulated that in anterior urethritis it will always inject a quantity of liquid corresponding in size to the individual patient's urethra, and the inflammatory stage present, without forcing the sphincter. This, I believe, Dr. Englebreth of Copenhagen claims he has accomplished.

3. The discovery and manufacture of a drug of such bactericidal and penetrative properties that it will, if applied locally penetrate the tissues of the genitourinary tract, kill the bacteria, yet not injure the infected tissues.

4. Obtaining a drug of such strength and properties that, if administered internally, it will destroy the gonococci and its toxins, as quinin does the plasmodium of malaria, and mercury the germ of syphilis.

5. Obtaining an immunizing serum or antitoxin.

6. The discovery of a microorganism capable of growth in the urethra, yet nonvirulent to the host, but destructive to the gonococcus and a neutralizer to its toxins.

If, now, we consider each of these means rationally and without bias, we will discover that not in any one of them can we hope to find a panacea, but rather a form of treatment that unites the good qualities of each; and will so control this disease that in the time to come, future generations will either not know gonorrhea, or will only know it in a modified form, and robbed of its serious consequences, as we today know smallpox, syphilis, etc. I believe that we will live to see the idea of the specific consistency of germs uprooted, and as a result the future genitourinary surgeon will also be a physician, who will devote time to the systemic treatment of gonorrhea, with the object of destroying the gonococcus, through increasing the bodily resistance to that organism. The local treatment, and the syringe, will be only one of the means to the end, and not the main road to a universal panacea.

THE SUBSTITUTION OF POTASSIUM CYANID FOR AMMONIUM CARBONATE, WITH FATAL RESULT.

BY

P. S. DONNELLAN, M.D.,
of Philadelphia.

To the Editor of American Medicine:—I have read with much interest in your issue of February 24 your editorial comment regarding the dramatic suicide of Whitaker Wright in a London Law Court recently, and your incidental reference to the fatal mistake of the substitution of potassium cyanid for ammonium carbonate in a prescription which occurred in Dublin a third of a century ago.

Perhaps it may interest your readers to know that the Dublin patient referred to was the head of the celebrated Guinness family of brewers and philanthropists. He had been ill with acute bronchitis and, as you correctly state, was given a prescription by his physician for a mixture containing ammonium carbonate. This was dispensed by the leading apothecary of the city, but the patient died a few minutes after taking the first dose. A rigid inquiry followed, with the result that the mistake was discovered to have been made when the ammonium carbonate bottle in the dispensary department was found to have been empty some days previously and was filled from the bottle in the stock room, but in doing so potassium cyanid was substituted by mistake, so that when the drug clerk dispensed the Guinness' prescription, he, unknowingly, gave the fatal drug, for the bottle was labeled "ammonium carbonate," and he was deceived by the similarity of appearance and by the presence of the odor of the nonpoisonous drug which clung to the dispensing bottle.

This was a *cause célèbre* at the time and for many years after was always a favorite theme in the course of lectures on Materia Medica in the Dublin medical schools.

INSPECTION OF SERUM AND VACCINE PRODUCTS.

BY

M. T. NAUGHTON, M.D.,
of Chicago.

To the Editor of American Medicine:—In your issue of November 14, Dr. Evans, of West Virginia, says, "he has been informed that the U. S. Government requires inspection in all of their departments of all establishments in which toxins, antitoxins, vaccines, etc., are prepared, and that interstate traffic in biologic products prepared in establishments having no such inspection is prohibited." This, unfortunately, is not true, but there is no doubt in the minds of medical men using such preparations that it should be so, and that such inspection by the Federal Government is absolutely necessary in order to standardize dosage, control the technic of manufacture, and to see that the laboratory animals are free from mixed infections.

The Bureau of Animal Industry of the Department of Agriculture, acting under authority of the Interstate Commerce act and other Federal laws, is at present engaged in the most extensive hygienic task of any sanitary corps in existence. Every pound of meat and other animal product intended for interstate trade, is rigorously inspected, and millions of pounds of diseased meats are condemned and converted into fertilizer every year. (See Dr. D. E. Salmon's reports, Washington, D. C.) This supervision is done without interfering in any way with the packer's business, except to see that his finished product is fit for food.

The law that gives authority for this kind of work also gives the department power to regulate interstate traffic in biologic products.

At present there is no disinterested supervision of the marketing of this line of animal products. We can only rely on the commercial honor of manufacturers that the article is what they represent it to be. We have no alternative but to take their word, and many times it appears that our confidence has been misplaced. We do not get expected results, sometimes we are unfortunate enough to have a patient die, the direct result of contaminated serum medication. I have seen very bad results

of vaccination in the hands of careful men, who relied on the product they were using. Last summer, for instance, I was exposed to smallpox, and thought it would be well to vaccinate myself and my child. Both of us were thoroughly septic as a result, in spite of modern treatment.

Again, diphtheria has been robbed of its terrors by the serum treatment. After an experience of over 1,000 cases so treated, I regard an honestly prepared diphtheric serum as near a specific as that term can imply, but there are many brands on the market. We cannot always get what we want in the shops. We may not have the time to wait, so we use what we can get; oftentimes it seemed to me that I was using inert sterile horse soup, so far as physiologic action was concerned. This should not be so. Every single dose of virus or vaccine should be certified to by the Federal Government, so that the man in Oregon can have just as reliable a product as his colleague in New York.

I am sure reputable houses would welcome supervision of this kind under such regulations as the department may see fit to prescribe.

Our desks are covered with literature advising patronage of some new firm that supplies a "splendid" article cheap. We have no reason to doubt the statements of the heads of those concerns at the time the article is purchased, but we do know that their products differ. We do know that commercial honor is a peculiar thing, and that department managers must show a profit to the owners of the establishment or quit. Let us urge the government to take this very important matter up at once, for the protection of the patient, ourselves, and the manufacturers.

RÖNTGEN RAY TREATMENT OF PATIENTS.

BY

WILLIAM S. NEWCOMET, M.D.,
of Philadelphia.

The treatment of patients by the röntgen ray is extremely tedious, when one patient after another must be protected by an individual screen, and each given a period of 10 minutes for the exposure. This most annoying obstacle is removed to a great extent by the use of a protecting screen, such as described below. The time of a competent operator is valuable, and when the röntgen ray has been employed by those who do not understand the working of the apparatus and the effects upon the system, poor results have usually followed, and those in charge have become discouraged, and the whole matter dropped.

While these points are in favor of the operator, there are just as many in favor of the apparatus; the tube, for instance, which is always subjected to such rapid degeneration, will do more work than when only one patient at a time is treated, and since it has been proved that the röntgen ray generated in all the active portion is about the same intensity, there is no reason why the whole portion of this light should not be used. This also saves the contact, of the coil, and no more electric energy is needed to treat 4 patients than would by ordinary methods be used in treating 1 patient.

The frame is made of wooden strips about 2 inches wide and 5 feet 5 inches high, the distance from the 2 sides is 20 inches; this makes a center of 10 inches; the front will give 2 more sides of 12 inches in width, 10 inches from a common center; the back is left open for the operator to work the apparatus, and at the same time he can see the proper exposure of the area to be treated, which cannot be done so readily by the other methods. If this frame were complete in the back it would be a regular 6-sided prism. The whole frame, or at least the active part, is covered with lead, and in this lead windows of varying sizes are cut; these windows have smaller sheets which reduce the size to the desired opening for the individual case. The tube holder is fastened to the side of the frame, and should have several universal joints which will allow the tube to be set at different positions beside varying the distances between the different sides, should this be desired; for instance, by moving the lamp forward to within 6 inches to the 2 front sides, it will still be 10 inches between the 2 lateral

sides. For the sake of privacy, movable frames are made to fit at the 3 corners. These can be covered with some material that will give all the privacy of separate rooms; these frames should be fastened with a hinge that is easily detached.

Beside the use of this frame in the treatment of patients, it can also be used for fluoroscopic examinations, the patient fixes the part to be examined before the window, then the fluoroscope is placed against the part; in this way the operator is not exposed to the ray, and therefore he is less likely to suffer from the burns that are so frequently seen.

This reason alone should recommend the use of some apparatus such as I have described.

AN INTERESTING CASE OF LAPAROTOMY.

BY

R. H. VON KOTSCH, M.D.,
of Chicago.

To the Editor of *American Medicine*:—I desire to report the following case, which may prove of interest to some of your readers.

Recently, a meat dresser in the Chicago packing house of Swift and Company, performed a laparotomy on a common Minnesota cow. The abdominal incision brought the stomach into the field of operation, and upon incising the wall of this organ, a hard solid mass, covered with a slight coat of mucus, was found in the stomach. The mass was shaped like a cricket ball, and weighed nearly 14 ounces. Inspection showed that the ball consisted of particles of grass, hair, no less than 1,000 ordinary pins, and 2 good-sized nails. The pins were all bent in a most peculiar way, points were all inward and heads toward the outer surface of the ball.

Conjecture is rife as to the presence of the metal ball. A plausible theory is, that the bovine, while grazing, picked up a package of pins, or perhaps 2 or 3 packages. These succeeded in reaching the stomach, and, in the process of digestion, formed the spheric mass.

LICENSURE.

BY

D. J. M. MILLER, M.D.,
of Philadelphia.

To the Editor of *American Medicine*:—The concluding clause of Dr. Sheets' letter on "Licensure" in your issue of December 26, 1903, that in three instances he has known registered pharmacists to interpret the Latin preposition *ad* as an abbreviation of the English word *add*, and so incorrectly compound prescriptions is, it seems to me, worthy of notice.

Twice have I met pharmacists who entertained the same misconception of the Latin word. In one case the offender was a registered pharmacist, the proprietor of a small shop in a portion of the city occupied by artisans, small tradesmen, and mill workers; in the other, he was not registered, conducting a moderate prescription business at a seaside resort.

How many more, as ill-informed as these two, are compounding prescriptions under the ægis of the boards of licensers I do not know—I hope and believe but a few; that at least five are so doing is shown by the experience of Dr. Sheets and myself.

The passing of such men by colleges and licensing boards is an evidence that these bodies do not scrutinize rigidly and thoroughly enough the acquirements of the candidates who come before them.

Tenth International Congress of Ophthalmology.—The committee of the Tenth International Congress of Ophthalmology has charged Professor Dr. A. Siegrist, Bern, Switzerland, with the preparations for the appropriate exhibition of all scientific apparatus, instruments, and the various appliances for instruction, which will be sent to the Congress. He therefore requests all colleagues, as well as all scientific, optical, and mechanical firms who wish to exhibit any objects at the International Ophthalmological Congress in Lucerne to apply to him before July 1, 1904, giving an exact statement of the object to be exhibited, of the space demanded, and of the kind and strength of electric force which may be required. Objects, which are announced later, can only be accepted as far as the space at disposal will still allow.

RECENT RESEARCHES IN RADIOACTIVITY AND ELECTRICITY. THEIR BEARING ON RADIO-THERAPY. LEGAL STATUS.*

BY

J. SHERMAN WIGHT, B.S., M.D.,
of Brooklyn, N. Y.

Assistant to the Chair of Operative and Clinical Surgery at the Long Island College Hospital Medical College and Assistant Visiting Surgeon to the Hospital.

A new era began in surgery with the discovery of the röntgen rays. The cathode rays, röntgen rays, and radioactivity, now promise to play as important a part in the therapeutics of malignant growths, in fact, have already shown potent effects on the metabolism of the cells of the body. Recent investigations with radiations, in which the electric properties of gases have played an important part, have given an insight into the nature of these radiations. A review of this work will give us some knowledge of what they have in common and enable us to discover how far this is effective in bringing about therapeutic results claimed for each in turn.

The discovery that the incidence of ultraviolet light on a spark gap facilitated the passage of the spark led to investigations on the effect of ultraviolet light on charged bodies.¹ It was proved that some metals lost their charges when ultraviolet light fell upon their surface, while if this surface was uncharged to begin with, it acquired a positive charge.² Sunlight is not rich in ultraviolet light rays as these have been absorbed by the atmosphere. The ultraviolet light is obtained from an arc light (carbon or iron terminals), burning magnesium, or by sparking with an induction coil between zinc, iron or cadmium terminals.³ These rays affect the conductivity of gases. In high vacua, metals when illuminated with ultraviolet light give out corpuscles, *i. e.*, bodies whose mass is only $\frac{1}{1000}$ of that of the hydrogen atom and their velocity through any gas is very approximately the same as that of the ion produced by the röntgen rays through the same gas.^{4,5} The photoelectric effect is diminished when the pressure is low by a transverse magnetic field.⁶

Radium gives off rays that are deflected when placed in an electric field and hence carry a charge of electricity.⁷ It also gives off nondeviable rays that are absorbed by aluminum foil. Heating has an enormous effect on the issue of the emanation from radium. In order to determine an increase due to heat, the radium is placed in a platinum tube, a constant current of air is passed over the radium and through a testing vat in which the saturation current is measured, the latter is due to the ionisation of the air in the vat, by the radiation from the emanation and also by the induced radiation of the walls of the vessel which become radioactive. On heating the platinum tube red hot the current increases 5,000 times. The emanations are found to be but very little increased over those in the cold state, on cooling the radium down and reheating after a few hours.⁸ This is due to a radioactive gas which has been found to exist in radium and has a molecular weight between 40 and 100, while the molecular weight of

radium is 225, so this gas cannot be radium. Rutherford and Soddy* give strong reasons for supposing that radioactivity is the result of the breaking up of the atom; thus the radium atom breaks up at first into the positively electrified particles which constitute the α rays, the emanation, and possibly other substances; the emanation breaks up, one of the products being the substance which gives rise to induced radioactivity, this, as it is radioactive breaks down again into products which, since they are not radioactive, have not been detected. It has been found that a strongly negatively electrified body suspended in the open air becomes temporarily radioactive. It will ionise the air in its neighborhood and affect a photographic plate. This body can be a conductor or insulator.⁹ This induced radioactivity falls to about one half its value in three quarters of an hour. It is more penetrating than the rays from substances made active by the thorium emanation, or than the nondeviable rays from thorium and uranium. The emanation from

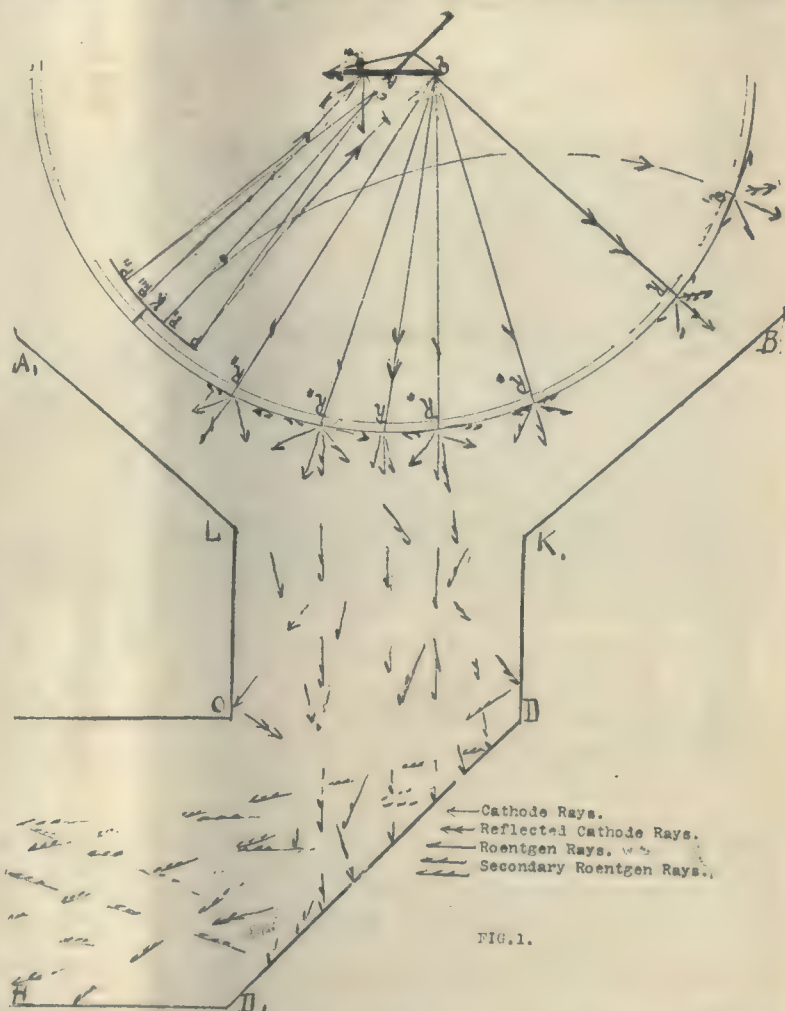

FIG. 1.

thorium will be attracted to a body charged with negative electricity and the induced radioactivity will be concentrated on this body at the expense of that on surrounding objects. C. T. R. Wilson has observed radioactivity in freshly fallen rain and the rate at which it dies away is about the same as that on a negatively electrified body. The radioactivity of rain and a negatively electrified body is induced radioactivity. Elster and Geitel ascribe the induced radioactivity to the deposition on the body of some radioactive substance which is diffused through the atmosphere as that product

* Read before the State Medical Society, January 27, 1904, at Albany, N. Y.

* Phila. Mag., Vol. vi, p. 576, 1903.

to the surface of the cathode, so we have negative ions starting from close to the surface of the cathode; these are driven from it with such velocities that they ionise the gas through which they pass, producing a supply of positive ions which are attracted by the electric field up to the cathode, there to produce a fresh supply of negative ions. (Fig. 1.)¹⁰ (There will be no cathode rays arising from that portion of the cathode in the shadow of a body interposed between the cathode and anode.) M. Villard proved in 1899 that the cathode rays are negatively electrified corpuscles— $\frac{1}{1000}$ of the mass of the hydrogen atom and their velocity through any gas approximately the same as that of an ion produced by the röntgen rays passing through the same gas.

The impact of the cathode rays produces chemie changes on the haloid salts of the alkali metals, and they exert a reducing action on oxidized plates. The thermal effect is sufficient to raise platinum to incandescence, fuse glass, and char the surface of a diamond, when placed at the point of concentration when a portion of a spheric shell is used as the cathode. The thermoluminescence exhibited by certain substances, *i. e.*, the power of becoming luminous when the temperature is raised to a point far below that at which they became luminous when in their normal state, after exposure to the rays, is regarded as arising from the ionisation of the substance, causing complex substances to be formed, stable at ordinary temperatures, but unstable at high temperatures, decomposing and producing thermoluminescence. The phosphorescence of some gases, especially those which polymerize with great ease, which is observed after electric discharges have passed through them would be due to the formation of complex molecules unstable at the temperature of the room.¹¹

When the cathode rays strike the surface of either a conductor or an insulator, cathode rays start from the surface in all directions. This reflection is very diffuse, but greatest in amount in the direction in which the angle of emergence is equal to the angle of incidence.¹² The velocities of many of the reflected rays are much less than those of the incident rays. The surface struck by the cathode rays emits secondary rays of lower velocity which is in many respects analogous to the emission of corpuscles from a body illuminated by ultraviolet light. The corpuscles of the primary rays penetrate some little distance below the surface ionising the molecules against which they strike; the secondary corpuscles produced in this way, and perhaps also some of the primary ones whose motion has been reversed by collision with the molecules of the reflector, escape from it and form the reflected rays.

Lenard proved the transmission of the cathode rays through solid bodies by showing that the rays transmitted through aluminum and coming from the cathode of a vacuum tube were deflected by a magnet and by an electric field, and carry a negative charge of electricity, proportional to the mass of the carrier and of the same value as for cathode rays.¹³ The cathode rays are deflected by an electric force, hence as the electric field is very intense in Crookes' dark space, the rays as they pass through this space will be deflected, even if the lines of force are straight and their paths will not quite coincide to the normals to the cathode at their point of projection. Deflection also occurs with converging rays from the cathode, due to the electrostatic repulsion of the negative electricity traveling along the cathode rays by the strong electric field which surrounds the cathode. Since the cathode is an equipotential surface, and if the corpuscles leave that surface normally and with equal amounts of energy, their paths will, by the principle of varying action, be the orthogonal trajectories of a system

of surfaces. Corpuscles are projected from an incandescent metal or glowing piece of carbon, the same carriers as the cathode rays, these are negatively electrified bodies of constant mass, and in all cases yet investigated, act as the carriers of negative electricity in high vacua. When they pass through a gas, moving at a high rate of speed, they make it luminous.

It has been shown that the spot struck by the cathode ray is the place where the röntgen rays originate, by taking photographs of a card pierced with pinholes, and drawing lines joining the photographs of a hole with the hole itself, and finding their point of intersection. Thus, when the cathode rays strike the walls of the tube, the phosphorescent part of the glass is the origin of the röntgen rays. (Fig. 1.) Those rays that impinge normally are more effective in producing röntgen rays than those which strike obliquely, absorption taking place through a greater depth of the glass, so that when the cathode rays strike against a plane area the röntgen rays come off approximately uniformly in all directions.¹⁴ This explains the uniform effect of the röntgen rays on a hemispheric photographic film placed so that its border intersects the plane of the platinum disc. The röntgen rays incident on a spark gap facilitate the passage of the spark. They ionise gases, increase the electric con-

Effect of primary rays from concentrator on a photographic plate

ductivity of badly conducting liquids, and the electric absorption of solids.²⁵ Diffractive effects have been shown similar to the diffractive fringes with sunlight, corresponding to the order of thickness of the discontinuous pulse. When röntgen rays pass through a substance they cause it to emit röntgen rays called secondary rays, which in many cases are different from the primary rays which produced them. This substance may be solid, liquid, or gas. More rays are produced when the primary rays impinge on a metal plate than when rays of the same intensity pass through air without coming into contact with the plate and the saturation current is higher when a lead plate is used.¹⁵ These secondary rays are detected by their action on a photographic plate. I have obtained them for therapeutic use by enclosing a tube generating röntgen rays in a metal box having a window opening into a metal tube to confine the rays, called a concentrator.

PLATE 1, shows both the exterior and interior views of this metal box m'bdrrh" with the concentrator A'A'L/Lt in position. The interior view shows that portion of the back of the metal plate, A'A'L/L, that fits into the square opening in the metal box with the metal ring that carries the projecting arms, aaaa, that hold the concentrator fast by drawing the projecting surface of the plate A'A'L/L, as appears in the exterior view, tightly against the outer surface of the box. Turning the arms through an eighth of a revolution releases the concentrator.

Fig. 2, shows a vertical section through the long axis of the

concentrator. The plate A' LK' B is in contact with the outer face of the box, JJ', and the arms aa are in contact with the inner face. This holds the concentrator in position. The elbow mx D' H F D' m' is shown on the end of the tube, LDK' O. The paraffin block, ETT' E', makes an angle of 45° with long axis of the tube. The cap, nzz' n', carrying the adjustable diaphragms, gsg', is on the end of the elbow tube and gives exit to the rays through the opening, wg". The advantage of using a conical tube concentrator is so small as to be disregarded.

The röntgen ray tube placed in the metal box opposite the opening into the concentrator at LK' projects the röntgen rays along the paths /. They impinge on and penetrate below the surface of the paraffin block, ETT' E' and give rise to the secondary röntgen rays /- that pass out through the opening wg'.

PLATE 2, shows several views of my concentrator with attachments and the effects on a photographic plate of the pencils of both primary and secondary röntgen rays, the latter after passing through $\frac{1}{8}$ mm. of aluminum. I have found these secondary rays valuable in treating healing surfaces left by the removal of malignant growths and the delicate structure formed in the repair of grafted surfaces. The concentrator protects patient and operator.

A cap of one to three thicknesses of tin-foil is used to sift out the soft rays in applying primary röntgen rays to affect deep structures, as it will be seen (vide infra) that the soft rays never touch them, but burn the surface.

We may compare the effects produced when röntgen rays fall on a metal plate with those produced by the incidence of ultraviolet light; *vide supra*, in both cases cathode rays are emitted by the metal. The secondary röntgen rays may be compared with the reflected light given out by certain substances under the influence of ultraviolet light, for which the reflected light is the same quality as the incident light. The secondary rönt-

Effect of secondary rays produced as indicated and passing through $\frac{1}{8}$ mm. of aluminum, on photographic plate. 6, secondary röntgen rays from lead plate. 7, secondary röntgen rays from paraffin block. 8, secondary röntgen rays from brass plate.

gen rays are not of the same nature as the primary rays, being much more easily absorbed. On account of the great absorption of the secondary and cathode rays, the layer from which they come must be very close to the surface. Langevin* has investigated the secondary radiation produced when the primary rays fall upon a metallic surface, and has shown that the denser the metal the smaller the penetration of the secondary rays, and also that the penetrating power of the secondary rays increases with that of the primary. J. J. Thomson has shown that the amount of energy radiated away in the röntgen pulse varies inversely as the thickness of the pulse, and the thickness of the pulse depends on the abruptness with which the particle is stopped; if the stoppage is very abrupt, the pulse is thin, if it is gradual, it is thick. The thin pulses move with a high velocity, and go much further before losing their energy, and would, therefore, be more penetrating. It follows that the penetrating rays affect the tissues of the body only in proportion to their loss of energy in passing through the body. This loss is gradual, therefore the total energy of one pulse is not given up at any one point of its path. The thick pulses lose all their energy in their passage through the skin. On the electromagnetic theory of light, the pulses which we suppose to constitute the röntgen rays are in many respects identical with the rays of visible light; both consist of electric and magnetic forces at right

angles to each other and to the direction of propagation; the difference between the röntgen rays and a beam of sodium light is that the thickness of the röntgen ray pulse is very small compared to the wave length of sodium light, and that in the röntgen rays there is not that regular periodic character occurring in a train of waves of constant wave length. Blondlot has shown that there is in addition to the röntgen rays, a new type of rays, which he calls the N rays, given off by the röntgen ray tube. These rays are also emitted by incandescent burners and sparks, they are refracted, and are apparently very long, some measured by Sagnac had a wave length of one-fifth millimeter. When these rays fall on incandescent platinum they increase its brightness without appreciably increasing its average temperature.

In Fig. 1. the cathode rays starting from P, P', P'' are deflected by the electric field in Crookes' dark space, and do not follow the normals to the cathode at these points. If the pressure in the tube is not very low, the paths of these rays will be along the radii of the cathode, and will be brought at a focus at the center C. If the platinum disc is at this point, it will be heated white hot, and the efficiency of the tube in röntgen rays will be very small or nothing. When the pressure of the gas in the tube is within certain limits, the cathode rays do not form a solid pencil, but are condensed into a hollow conical shell. The deflection of the cathode rays depends mainly upon the rate at which the intensity of the electric field diminishes as we recede from the cathode. When the pressure is lower, the field changes slowly as we recede, as the exhaustion is increased, the deviation of the rays is greater and the focus gets further from the cathode. The path of the cathode ray will not be along the normal PC, but along PQ somewhere

between the normal and the line of force in the field. There will be a diffuse reflection of cathode rays at Q resulting in the less intense cathode rays QR, which on coming in contact with the phosphorescent parts of the glass at R cause the emanation of röntgen rays and still weaker cathode rays, while some of the reflected cathode rays from Q pass on through the wall of the tube. Q will also be the origin of the röntgen ray QR' which passes through the wall of the tube at R'. R' also becomes the origin of secondary röntgen rays and cathode rays. All the rays take straight paths from Q, since they leave the surface of a plane disc. P'Q' will be the path of a cathode ray when the focus has receded still further from the cathode. It will be effective in producing röntgen rays at the phosphorescent part of the glass where it impinges as well as cathode rays. If the metallic elbow-tube A' LOFBKD' D'H is placed to receive the röntgen rays emanating from the surfaces of the tube and the platinum disc within the tube on the lead plate DD', secondary röntgen rays will emanate from their points of contact with this plate as well as from beneath its surface. Cathode rays are also given off; the plate emits negative electricity and acquires a positive charge. Most of those coming from below the surface will be absorbed during their exit, as they must travel through the same distance as the original ray producing them, and are much less penetrating. If a solid block of paraffin replaces the lead plate, the secondary rays will be more penetrating than those coming from the lead plate in the proportion of 15.5 to 6. The paraffin is less dense, and the secondary rays meet less resistance to emergence.

Some röntgen ray tubes have a small auxiliary tube attached, which gives emanations that ionise the gas in the main tube before the discharge takes place in it; they also contain a salt that gives off water vapor or other gaseous impurity in the main chamber of the tube, which as well as the ionisation, increases the conductivity of the gas in the tube. While in operation these tubes maintain a fairly constant rate of change in the intensity of the field receding from the cathode. They can also be operated at different values for the conductivity of the gas in the discharge tube, giving hard or soft rays, at the will of the operator, within certain limits. With a given low pressure in the tube, the röntgen rays increase as the electric energy supplied to the tube increases, till the cathode rays are projected from the entire concave surface of the cathode and the rim of the bowl. The rate at which the intensity of the field changes as we recede from the cathode is slow and

* Recherches sur les gaz ionisés.

the focal point is the same distance from the cathode, whether a portion of the cathode or the whole cathode is giving off cathode rays. The kinetic energy at the focal point would be greater when cathode rays are being projected from the whole surface of the cathode. The shorter the radius of curvature of the cathode, the nearer the focal point, and the lower the pressure required in the tube to cause it to recede to a point on the platinum disc. The increase in röntgen rays with an increasing supply of electric energy to the tube goes on till it is at a maximum, when the platinum disc is a dull red heat and falls when it becomes a yellow heat. The cathode rays leave the cathode at a very great velocity. Their collisions with the molecules of the gas cause secondary cathode rays to be formed. The intensity of cathode rays therefore increases up to a certain distance from the cathode and then diminishes beyond that point. This place varies with the velocity with which the corpuscles are shot out from the cathode. The higher the vacuum in which the discharge takes place, the greater this velocity, therefore this point would change with the pressure. If the cathode rays should come to a focus at a distance from the cathode where this maximum of intensity is attained, the kinetic energy at this point would be enormous. Beginning at a very dull red heat, there are positive ions around the platinum disc, and these increase as the temperature increases. Negative ions, however, do not make their appearance until about a bright yellow heat; they increase more rapidly with the temperature than the positive ions, until at very high temperatures there are as many negative as positive ions, indeed, the number exceeds that of the positive ions.²⁶ Thus, the temperature of the platinum disc limits the increase in intensity, and finally diminishes the supply of cathode rays. A water-cooled platinum disc lessens the injurious effect of heat to some extent. Since the cathode rays come from the surface of the cathode, the larger the surface projecting them the more rays in a unit of time. A strong magnetic force parallel to the line of discharge produces a large diminution in the potential difference required to spark through the tube. This can also be produced by covering the tube in the neighborhood of the cathode with tinfoil connected with the cathode or by grounding the cathode terminal.

The secondary radiation is explained if we take the view that the röntgen rays consist of exceedingly thin pulses of very intense electric and magnetic force. Suppose that such a pulse is traveling through a medium containing ions, it is not necessary that the ions should be free; when the pulse reaches a charged ion, the ion will be acted upon by a very intense force and its motion accelerated. When the velocity of a charged body is changing, pulses of electric and magnetic force proceed from the body, the magnitude of these forces being proportional to the acceleration of the body; thus, while the primary röntgen pulse is passing over the ion and accelerating its motion, the ion gives out a pulse of electric and magnetic force, the secondary röntgen pulse; this ceases as soon as the primary pulse has passed over. There are several sources of loss of energy here. When we take into account the energy absorbed by the ions and neglect that radiated by them, the coefficient of absorption increases with the thickness of the pulse and the distance between them. The broader the pulses, the greater the absorption. The soft rays correspond to the broad pulses and the hard rays to the narrow penetrating ones. Tertiary rays have been obtained by allowing secondary rays to fall on a metal plate and correspond to still broader pulses.¹⁶

A striking analogy of the properties of ultraviolet light rays, cathode rays, röntgen rays, radioactivity, and electric discharges appear in this review. This, together with the results of investigation here set down, suggest more practical methods for their application in medicine and surgery, and their bearing on the constitution of the living cell will appear in a study of its physiology.

The metabolism of living substances upon which all life is based, is conditioned by the existence of certain labile compounds which stand next to the proteids, and on account of their elementary significance in life are best termed biogens.²¹ We must imagine that by reason of the extremely active intramolecular motion of the atoms, which is the cause of the labile condition, certain atoms, partly spontaneously and partly as a result of external commotions, come under the influence of others, for which they possess greater affinity than for their original neighbors, and in this manner more stable groupings of atoms arise as independent compounds. In this respect the biogens can be compared to explosive substances, the atoms of which possess, likewise, very labile equilibrium, and which upon receiving violent shocks explode, *i. e.*, rearrange their atoms into more stable compounds.

The biogens agree in essential structure, but differ in

A, adjustable diaphragms, paraffin box, lead and brass plates for producing secondary rays. B, concentrator in position. C, inside of metal box, showing method of securing concentrator. D, cap, carrying diaphragms in position. E, elbow tube for secondary rays in position. F, concentrator and elbow; tube carrying diaphragms ready to produce secondary rays from paraffin box.

constitution in different cells and various differentiations of the same cell. The essential part of metabolism is the continual construction and destruction of biogens.²² It is known that by the introduction of oxygen the biogen molecule takes on an extraordinarily labile constitution, *i. e.*, its intramolecular heat becomes very great. As a result of this, the molecule tends toward decomposition and explodes, partly spontaneously and partly on slight external stimulation. This explosive decomposition depends upon a rearrangement of the atoms, whereby, as in all explosive bodies, within single atomic groups stronger affinities become united than were previously united in the labile molecule. Therefore, as a whole, the dissimilatory processes must be associated with considerable production of energy.

The compounds derived from this decomposition of the biogens which leave the body, such as carbon dioxide,

water, etc., contain scarcely perceptible quantities of chemic potential, while the compounds that remain in the body, the residue of the biogens, again possess chemic affinities for foodstuffs and oxygen, and employ them in uniting with the latter. The energy thereby made available is employed again for loosening the biogen molecule, and thus the chain ends. The principle upon which it is based is: There is a continual storing up of potential chemic energy and a transference of it into other forms; the source of it is largely the food and oxygen; the original capital is the chemical energy that every minute droplet of living substance has carried over from its ancestors; and the result is expressed in the work accomplished by the living substance.

If we consider the quantitative relation of assimilation to dissimulation in a considerable mass of living substance, for example such as is contained in a cell, we

find it very variable and even without the influence of stimuli it changes within wide limits. This relation of the two processes in the unit of time, which can be

expressed by the fraction $\frac{A}{D}$ termed the biotonus, is of

fundamental importance for the various phenomena of life. The variations in the value of the fraction, effect all changes in the vital manifestations of every organism. The events that lead to the construction of the biogen molecule and the formation of the decomposition products are very complex and consist of many processes closely interwoven. In order to understand the effect of any stimulus on the biotonus we must know if it excites or depresses and to what component of biotonus the action extends, assimilation or dissimulation.

When every increase in assimilation results in a cor-

responding increase in dissimulation, the biotonus should be expressed in a specialized way and the fraction takes

the form $\frac{a+a_1+a_2}{d+d_1+d_2} = 1$, in which a, a_1, a_2 , etc., and

d, d_1, d_2 , etc., represent the partial processes that combine to form the whole, and the metabolic equilibrium continues to exist in spite of the absolute change in the extent of metabolism. This is the internal self regulation of metabolism. It has been found as to its behavior toward ingested nitrogen that with a definite quantity of ingested proteid, about 118 gr. in the laboring man, nitrogenous equilibrium continues to be maintained; i. e., the more nitrogen introduced in the proteid, the more is excreted in the urine, a sign that the dissimulation of proteid increases in the same proportion as the assimilation.²³ Internal self-regulation of metabolism does not exist everywhere and when it exists it is confined within certain limits, for if it were effective at all times and in all places, continual metabolic equilibrium would exist, and growth, development and atrophy would be impossible.

The biogens are labile compounds that polymerize readily, the atoms of their molecules are in active motion. As a result of this, certain atoms come occasionally into the sphere of attraction of others, and becoming united with them into a more fixed combination, separate off as an independent molecule. When the chemic affinities made available by the withdrawal of the separate groups of atoms have an opportune possibility of combining again so that the residue of the biogen can be rebuilt into a whole biogen molecule, spontaneous assimilation follows spontaneous dissimulation. Any increase in the intramolecular motions of the atoms assists the process of dissimulation. In this way the decomposition of living substance takes place under the influence of chemic, mechanical, thermal, photic, and electric stimuli, and if these external influences are so strong that no residue capable of regeneration is left there results molecular death of living substance. On the other hand, the process of dissimulation is depressed by all factors that diminish the intramolecular motion of the atoms, such as forces that fixate single atoms in definite position, substances do this by chemic attraction. All factors that favor the union of the available chemic affinities belonging to both the biogen residues and the complete biogen molecules themselves, due to their inclination to polymerize, increase assimilation, e. g., increased introduction of food material and production of ferments to make them soluble, oxygen, light to split up carbon dioxid in the green plant cells and make the carbon available. The changes that vital phenomena undergo may be either quantitative or qualitative. The metamorphic process of necrobiosis, typified by amyloid metamorphosis, shows clearly that here individual members of series A and series D must slowly and gradually change, independently of one another, otherwise accumulations of individual substances that normally do not occur in the cell cannot take place.

The most important physical characteristic of living substance is its liquid nature. There are deposited within the liquid all sorts of solid elements of very various consistencies, so that the whole constitutes a mixture, but vital phenomena are associated only with a liquid organization. All the structures that have a rigid consistency, like tendons, connective tissue fibers, cell membrane, and the ground substance of bone and cartilage, show no active vital phenomena, and the old dictum, "*corpora non agunt nisi soluta*," although its universality may be attacked here and there, applies perfectly to living substance.²³ There is a uniform solid organization of the cells that enter into the repair of lesions of the body. This has come about through the loss of the liquid nature of the living substance of these cells. Bearing on the loss of the liquid consistency, is the

capacity of clotting or coagulating, a physical property that belongs to almost all proteids, with the exception of their hydrates, the peptones, and is connected with their polymerism. Bearing directly on the nutrition of the cells, is the further physical property of diffusibility. The proteids in their polymeric form will not diffuse through membrane, on account of the very considerable size of the molecule. They are chain-like combinations of many similar groups of atoms. The single similar atomic groups that arise by hydrolytic cleavage have the chemic characteristics of the original combination, but are smaller and, therefore, diffusible. Thus repair and nutrition appear to be connected with polymerism. The application of ultraviolet light rays, röntgen rays, and electric discharges to areas affected in certain pathologic conditions, such as ulcers, lesions of skin diseases, lupus (cancer after operation), etc., relieves pain and often brings about repair. This is not recognized as connected with any of their familiar physical properties. Experiment has shown their marked influence in retarding osmosis. When röntgen rays impinge on the surface of the body the molecules and atoms lose negative electricity and acquire a positive charge, negative corpuscles are given off which may, of course, combine with the positive ions, the body is ionized. A pointed conductor brought near the body will cause a spark discharge. The available chemic affinities of both the biogen residues and the complete biogen molecules would be affected, polymerism would be increased, and fixation of the atoms would in some measure take place. It has been shown that when the röntgen rays pass through one layer of tinfoil after another, the absorption produced by the first few sheets of tinfoil traversed is much greater than that due to the same number of sheets after the rays have already traveled through several sheets of tinfoil. This shows that some of the rays are readily absorbed, while others pass through with great facility.²⁷ The rays that are readily absorbed are the ones that produce burns, and play the most important part in ionization.

We have already spoken of thermoluminescence of solids and the afterglow of some gases under the influence of these agencies. The afterglow has been found to be connected especially with those gases that polymerize with great ease as oxygen and cyanogen, and is only developed between the pressure limits of 6 mm. and .01 mm.²⁴ If the discharge is sent through the gas at a pressure not between these limits, there is no glow but if the discharge has ceased and the pressure is altered so as to come within the limits the gas at once begins to glow, suggesting that the polymerized form is stable; that is, does not go back into the normal form except between the limits mentioned. The conclusion is that the proteids and biogens as well as some gases contained in the tissues are affected in their polymerism. The further effect on the tissues is electrochemic, due to the acceleration of the charged ions.

I have been able to show that high frequency discharges will clot blood acting as a hemostat, and will coagulate serum albumin, but this is in some degree due to the formation of nitric acid from the air but there is no destruction of tissue with ordinary care. I have made use of this in sealing surfaces after the removal of small diseased areas especially in the neighborhood of bone and in fixing grafts to granulating surfaces the results of which have been so uniformly successful in my experience that I now ask attention to the technic of this method of electric grafting: Render the granulating surface sterile; prepare it to receive the grafts by curetting it thoroughly; and while it is still oozing place the grafts of any form desired in position on the surface and bathed in blood; apply the high frequency discharge from a pointed electrode over the entire surface till clotting is firm and the grafts are fixed on a dry surface. Serum that is squeezed out in the process of clotting should be sponged off. The dressing consists of

3% carbolized vaselin on plain sterile gauze. It is renewed at the end of the third day. The repair follows in the usual way but takes a shorter course. Repair was hastened in some cases in which the secondary röntgen rays were used at the end of the first week.

The following cases were subjected to this method of grafting:

CASE I.—A. N., aged 42, liquor dealer, 18 months ago was operated on for varicose veins of the left leg, and the ulcer on the leg healed in the course of 10 weeks. The ulcer reopened in 2 months, attaining the size of a silver dollar, and was treated with some improvement to October 26, 1903. It was then given a 3 days' preparation with soap, water, and dilute carbolic acid. Reverdin grafts were taken from the thigh and applied by the electric method. At the end of a week the healing surface was exposed to the secondary röntgen rays for 10 minutes. This was repeated at intervals of 3 days. Repair was complete in 3 weeks, and has remained so.

CASE II.—Mrs. T., aged 36, recovered from a cellulitis of the right leg with an ulcerating surface extending from the outer malleolus $3\frac{1}{2}$ in., down on the dorsum of the foot, and 2 in. in width. I grafted the surface with Thiersch grafts by the electric method, November 24, 1903. The secondary rays were not used till the beginning of the second week, and only repeated twice, 15 minutes at a sitting. Repair was complete by December 29, 1903. I have not seen her since.

CASE III.—W. B., aged 40, mate of a steamship, was admitted to the service of Dr. Bristow at the Long Island College Hospital, Brooklyn, October 11, 1903, suffering with ulcers of both legs, covering the front of the legs and extending around to the calves from the knee to the ankle. The small superficial veins were injected and the ulcers had increased in severity for the past 5 months. I saw him on November 27, 1903. There was a high degree of inflammation of both legs. I had them scrubbed with soap and water and washed with alcohol. The same day I grafted the surfaces of the ulcers of the left leg with both Reverdin and Thiersch grafts by the electric method. The next day I grafted the right leg. The dressings were not removed till December 2, when the secondary röntgen rays were applied for 10 minutes. The legs were not again exposed to the secondary rays. December 23, 1903, the right leg was healed, and January 11, 1904, he was discharged from the hospital with repair complete in both legs.

CASE IV.—O. A., aged 29, housewife. Varicose ulcer of right leg, just below the patella for 4 months. She was admitted to the service of Dr. Bristow at the Long Island College Hospital, December 11, 1903. December 12, 1903, ulcer was curetted and bone drilled under general anesthesia. December 22, 1903, the case was referred to me, and I grafted a surface $2\frac{1}{2}$ in. in diameter with Thiersch grafts by the electric method. The wound was dressed every third day till she left the hospital, January 3, 1904. She has since come to my office every week and had the healing surface exposed to the secondary röntgen rays for 15 minutes. January 25, 1904, the surface was not fully repaired; it measured $\frac{1}{2}$ in. in diameter.

CASE V.—E. S. B., aged 73, first noticed a growth on the tragus of the right ear, January, 1903. It grew larger to about the size of a small almond until August, 1903, when it broke down. It was still discharging December 29, 1903, when I saw him. I froze the surface with ethyl chlorid, cut off the growth with a pair of scissors, and curetted its base. The high frequency discharge was applied till the surface was dry, and a dry dressing put in place. January 4, 1904, the surface was again exposed to the high frequency discharge to fix a small graft in place. January 7, primary röntgen rays were used for 10 minutes. January 12, removal of the dressing started some oozing, and the high frequency discharge was again used. January 18, 20, and 23, the secondary röntgen rays were used for 15 minutes, and at the last visit repair was complete, leaving almost no scar. Microscopic examination of the specimen in this case showed the growth to be epithelioma. I shall endeavor to keep the patient under observation for recurrence of the growth.

CASE VI.—K. McQ., aged 60, housework. Admitted to the hospital November 17, 1903, suffering with a carbuncle at the back of the neck. Deep incisions were made November 18, 1903. December 19, 1903, the granulating surface, $3 \times 2\frac{1}{2}$ in. in extent was grafted by the electric method. No secondary röntgen rays were used in this case, and January 25, 1904 there is still a surface of 1 in. by $\frac{1}{2}$ in. left to heal.

It is evident that we are at present quite unable to review even approximately special changes that biotonus experiences in concrete cases under the action of these stimuli. For the present it is only possible to analyze step by step the outward expression of these changes.

The assumption of superior knowledge and skill in the application of the röntgen rays or radioactivity by some men has been noted and we may point out that this assumption tends to break down the wall that stands between what we can and what we cannot do.

The röntgen rays and the radiations from radioactive substances as well as the cathode rays have certain dangerous qualities inherent in their action on the tissues of the body. The benefit derived from their therapeutic application has passed beyond the experimental stage. The diagnostic value of the röntgen rays is on record. The question arises, how can we as medical men use these radiations for the purpose of diagnosis and therapeutic effect, and feel a full degree of security granted and secured by law? In the case of Bancroft vs. Perce, tried before the Superior Court in California, the defendant showed that he had fully given the plaintiff to understand before subjecting him to the röntgen rays that accidents had occurred from its use and might happen again, that people had been burned about the body. This was held to be sufficient warning. He had used an approved apparatus and had taken the precaution to protect the adjacent parts that were burned. A verdict was found for the defendant. Another case was tried in Paris against a medical man who had exposed a patient suffering with sciatica to the röntgen rays for 40, 45 and 75 minutes on three separate occasions. After the first 2 exposures the skin became red and inflamed and while in this state the third exposure was made. The apparatus was shown to be defective. The court found that he had acted more like a workman than a medical man, and directed a verdict for the full amount of damages. The records contain but few of these cases and there are, no doubt, points that have not as yet come up for the ruling of the presiding judge or the decision of the higher court, but there are some suggestions from those already tried that we shall do well to follow in this line of work.

We should be sure to use an approved apparatus and technic, and keep abreast of the progress in this field. Give the patient full advice of the risk of injury. Record the form of apparatus used, previous exposure to radiation, source, time elapsed since exposure, length of exposure, distance from the surface of the tube, time of exposure, register of penetration, form of protection to adjacent parts, and part exposed. Every plate should register the penetration in a picture of the gauge appearing on its border. If a blank form contains all that has just been outlined and is filled out by the operator and signed by the patient it will prove a valuable record of the case and have the force of a waiver in the event of litigation.

A röntgen-ray picture is admitted as competent evidence when the witness describes the apparatus, shows proof of every step in the making of the picture, identifying it in court whether it is a print or a direct positive, shows that he has looked with the fluoroscope and that the picture corresponds exactly to that seen on the screen. He must be prepared to say that he has operated and verified the condition represented by the röntgen ray picture of some deepseated injury in order to show that he has verified these pictures. He must further show that the picture represents the part claimed to be injured.¹⁷ A plan or picture, whether made by the hand of man or photography, is admissible in evidence, if verified by proof that it is a true representation of the subject, to assist the jury in understanding the case. Whether it is sufficiently verified is a preliminary question of fact, to be decided by the judge presiding at the trial and not open to exception.¹⁸ It has been held that after admission of röntgen ray pictures the negatives could be introduced in evidence at the instance of the opposing party to show that the pictures were incorrectly designated left and right.¹⁹

It will be seen from what has already been said of the penetration of the röntgen rays and the emission of secondary rays when the primary rays pass through a substance that the picture is a high-class photograph with not only outline, but the details and plan of the varying densities in the structures within the surface of the object, and is comparable in qualities of true imagery

with the best photography by reflected light. The difference between this and a shadow picture is a fact visible to the eye. The truth would appear on inspection of the given picture. The fluoroscopic examination alone is not admitted except when the picture could not be taken or is lost, and may then be excluded on the ground that the picture itself is the best evidence.²⁰

A CASE OF ACUTE LEUKEMIA, WITH DEATH DUE TO RUPTURE OF THE SPLEEN.

BY

JOSEPH L. MILLER, M.D.,

AND

JULIUS HESS, M.D.,

of Chicago.

Acute leukemia, first described by Friedreich in 1857, may be considered a rare disease, more prevalent, however, than the reported cases would indicate. Mixa,¹ 1901, collected 69 cases from the literature. The relatively large number of cases reported by some observers as Fraenkel, who in 7 years—in a yearly material of 4,500—saw 12 cases, indicates that those familiar with the clinical picture see the disease quite frequently; while others with equally great opportunities have never recognized a case. That the disease is frequently not diagnosed is probably true, as in a study of the cases reported it is in comparatively few that the correct diagnosis has been made in the beginning, but only after the development of unusual signs and symptoms leading to a more careful examination, has the correct conclusion been reached.

The characteristic symptom-complex is easily recognized, but atypical cases are frequent and it is only when we have constantly in mind the possibilities, that these cases are detected. Even when the unstained blood is examined, the moderate increase in the leukocytes with the associated fever, might lead to the diagnosis of inflammatory leukocytosis. The findings often differ so widely from those considered as typical for leukemia, that blood-examination is not made. The predominance of the hemorrhagic tendency, with local areas of necrosis in the mouth, and moderate lymphatic and splenic enlargement leads to the diagnosis of purpura hæmorrhagica. Gilbert and Weil report a case in which the onset resembled an infectious stomatitis. The epistaxis, splenic enlargement and fever have led to the diagnosis of typhoid or some obscure septic condition. Some patients find their way to the surgeon on account of the ulcerative processes in the mouth and the correct

diagnosis is only made on the autopsy table. We have seen a case of this nature. The marked anemia, often due to internal bleeding, has led to the diagnosis of chlorosis or secondary anemia.

The following is a history of our case:

Mr. S., American, aged 24, traveling salesman. Father died of heart disease at 60. Mother, 2 brothers, and 2 sisters are living and in good health. One brother suffered several years ago from tuberculosis of the ankle.

With the exception of a mild attack of typhoid fever 4 years ago, the patient has always had fair health. He denies luetic infection. He has used alcohol moderately, and tobacco to excess.

He first consulted a physician in October, 1901. He then complained of anorexia and severe abdominal pain, especially after eating, and was told that he suffered from acute gastritis. These symptoms continued with periods of intermission for 5 weeks, when he came under the observation of Dr. Hess. At this time he was complaining of pains in the lower abdomen, associated with pains in the epigastric and lumbar regions, anorexia, and marked flatulency and malaise. No history of hemorrhage.

Physical Examination.—Patient is emaciated; skin and mucous membranes pale. Slight but general enlargement of the superficial lymphatic glands. Slightly impaired resonance over the right apex; lungs otherwise normal. Heart normal boundaries, tones faint, soft systolic murmur over the pulmonary area. Liver border palpable, smooth, normal consistency, and not tender. Spleen barely palpable. The abdomen is uniformly distended, giving a tympanitic note, with no signs of free fluid. Patient says he has had difficulty in buttoning his trousers on account of the enlargement of the abdomen. No tumor palpable. The urine is free from albumin. The sputum negative for tubercle bacilli.

Under light diet and free catharsis the patient showed marked improvement, and was not seen until 3 weeks later, November 14. He was then in bed, and complained of severe pain in both hips and region of the crest of the ilium. Moderate doses of salicylate relieved the patient somewhat.

November 18: The patient still had pain in pelvic bones. Very severe epigastric pain. Slight pain in the sternal region. The liver and spleen were larger than at previous examination; otherwise the findings were unchanged. A tentative diagnosis of tuberculous peritonitis was made.

November 19: We both examined the patient. Temperature, 101°. Patient very anemic. For several days he has noticed marked epistaxis and bleeding from the gums. Nostrils contained clotted blood. Slight oozing from the gums, no ulceration or swelling of the alveolar mucous membranes. Cervical lymphatic glands are the size of a date seed, soft and painless. Axillary and inguinal glands present about the same enlargement. Ecchymotic spot, about the size of a half-dollar, on inner aspect of the right knee. Numerous petechial hemorrhages. Marked tenderness over the sternum and some of the ribs. None over the bones of the extremities. Lungs and heart as in previous examination. Abdomen very much distended, tympanitic, no signs of free fluid. On account of the marked distention and tenderness, deep palpation was impossible. Liver edge, 3 fingers below the costal arch, smooth, painless, and of normal consistency. Spleen, on deep inspiration, extends 2 fingers below the costal arch, smooth, soft. Rectal examination negative. Urine free from albumin; no blood; no casts. A fresh specimen of blood showed considerable leukocytosis. A white count gave 50,000 leukocytes.

The leukocytosis, with the other findings, led us to make a probable diagnosis of acute leukemia, pending a more complete blood-examination. This was made the following day. Leukocytes, 50,000. Erythrocytes, 2,800,000. Hemoglobin, 48%. A differential count of 200 leukocytes. Small lymphocytes, 4%; large mononuclears, 84%; eosinophiles, 3%; myelocytes, 1%; polymorphonuclear neutrophilic cells, 8%. Numerous nucleated reds, chiefly megaloblasts, many of these showing mitotic figures.

November 20: Dr. Hess was called at 4.30 a.m., and found patient in collapse; cold perspiration, small rapid pulse, labored breathing. Patient reported that during the night he had attempted to go to the bath-room. On the way he fainted and fell, and when found was in this state. Under stimulation, he improved somewhat. At 10 a.m. he vomited bile-stained mucus containing small clots of blood.

November 21: Patient began sinking rapidly about 5 a.m., and 500 cc. of a normal salt solution was injected subcutaneously, without noticeable effect; patient died during a fit of vomiting at 10.45 a.m. Blood-examination and cultures just before death gave 2,849,000 erythrocytes, 48% of hemoglobin, 161,600 leukocytes. Differential count showed 78% large mononuclears, 4% small lymphocytes, 3% of eosinophiles, 2% of myelocytes, 13% of polymorphonuclear neutrophils, and numerous megaloblasts. Cultures were negative.

Autopsy 10 hours after death by Dr. Otto L. Schmidt and the essayists. Body anemic and poorly nourished. Several large ecchymotic areas on the lower extremities. Heart dilated, muscle pale and friable, valves normal. Cicatrix in both apices. No enlargement of the mediastinal gland. Peritoneal

cavity filled with clotted blood. Right lobe liver 20 cm. by 25 cm. Normal consistency. Markings indistinct. Spleen 10 cm. by 15 cm., soft and pulpy. On the anterior superior surface are two tears about 3 cm. in length, extending deep into the parenchyma, the edges coated with lymph. In the same region is a small circular area of necrosis about 1½ cm. in diameter, its base and edges thickly coated over with lymph.

Just below the stomach in the omentum was a small hazelnut-sized body, with color and consistency of the spleen. Later microscopic examination demonstrated this to be an accessory spleen.

Kidneys normal size. Capsule free, with the exception of a small infiltrated focus in the left kidney, and the pallor of normal appearance. Pancreas normal appearance. Matted mass of postperitoneal glands larger than a man's fist along the lower lumbar spine. On section the outline of the individual glands was well marked. Several glandular tumor masses in the mesentery and the omentum.

Appendices epiploicae are very large, due apparently to lymphoid infiltration. The presence of these along the rectum compressed the posterior wall of the bladder. Stomach mucous membrane shows areas of lymphoid infiltration .5 cm. to 1 cm. in diameter, with central erosions forming small ulcers in the mucosa. Numerous submucous hemorrhages.

Portions of the intestines are adherent to the tumor mass in the omentum and along the spine. A long ileocecal intussusception; a large infiltrated Peyer's patch about 25 cm. above ileocecal valve being the apparent cause. Marked hyperplasia of Peyer's patches and small scattered areas of infiltration, many with necrotic centers giving a crater-like appearance. Numerous submucous hemorrhages.

Bone marrow: Sternum and ribs reddish-gray, and on microscopic examination, a count of 200 cells failed to show a single granular cell. Large mononuclear cells, resembling those in the blood, predominating. Many of these closely resemble myelocytes without the granules.

Histologic Findings.—All the organs showed a diffuse lymphoid infiltration with a large cell resembling those found in the blood. In the kidneys small areas of infiltration abound, the kidney tubules in many places being compressed, the glomeruli escaping. The infiltration in the liver is mainly interlobular. Some areas were found where the liver structure was almost obliterated, only a few liver cells being found. There was a diffuse infiltration of the wall of the stomach, most marked in the mucosa; the glandular structures in many places obliterated.

The clinical symptoms, blood condition, and the autopsy findings are those of an acute leukemia. It is difficult to determine whether the rupture of the spleen was due to the fall or whether it antedated it. The extreme dizziness of the patient on his attempt to go to the bath-room rather favors the presence of previous hemorrhage and, therefore, spontaneous rupture, as he had been walking about the day previous without special difficulty. The presence of two tears in the capsule favors its traumatic origin.

The etiology of all forms of leukemia is still obscure, but the acute course with the associated fever points to the probable infectious nature of the acute type of the disease. Obrastzow's² two cases, in which the attendant of a man suffering from acute leukemia developed the disease, is an isolated case and of slight significance. Several cases have apparently developed from a pseudoleukemia, *i. e.*, enlarged lymphatics and spleen without perceptible blood changes; later, the development of a leukocytosis, hemorrhagic tendency, and rapid death. Kuhn and F. Weiss³ report a case in which the clinical symptoms were those of a pseudoleukemia with a leukocyte count of 2,800. At the end of 8 months the patient received an injection of pilocarpin. The next day the patient had a leukocytosis of 22,800. Two days later a second injection of pilocarpin was followed by an increase to 24,000. Ten days later there was marked reduction in the size of the spleen and lymphatic glands with steady increase in the leukocytes, until at the time of death—one month after the first injection—they reached 146,000. The assigned cause of death was lympholienal leukemia. Wende⁴ reports a case which he considered a typical pseudoleukemia.

April 26. Red corpuscles, 5,128,000; leukocytes, 4,000; hemoglobin, 88%. Differential count of leukocytes gave 68% Polymorphonuclear, 27% lymphocytes. Under arsenic at first improvement, then rapidly worse with fever and hemorrhages. July 10: 1,936,000 red corpuscles; 34,000 leukocytes; 95.5% of the small lymphocytes. Death July 30.

Fleischer and Penzold,⁵ and Mosler,⁶ report cases in which an acute leukemia developed in patients with pseudoleukemia. We are not justified in these cases in

saying that a pseudoleukemia has become converted into an acute leukemia, but rather that a patient with pseudoleukemia has developed acute leukemia.

Two of Fraenkel's patients had just recovered from influenza. Eichhorst reports a case following whooping-cough. One case developed during the eighth month of pregnancy. In several cases a severe anemia has been reported preceding the onset, although in these cases the anemia may have been secondary to an undetected leukemia.

The proportion of males to females is about 3 to 1. In children under 10 years, 13 cases have been reported. Pineles⁷ reports a case in a patient of 73.

The onset may be very acute or may develop gradually, and no single symptom may be considered initial. A case of Eichhorst's⁸ began with severe sticking pain in the side, followed by hematemesis. In others the epistaxis, or bleeding from the gums, or hematuria first attracted attention. Areas of necrosis in the mouth often bring the patient to the physician. Severe joint pains, subcutaneous hemorrhages, fever and glandular swellings have all been reported as initial symptoms.

The most constant findings, exclusive of the blood changes, are the tendency to hemorrhage, focal necrosis, fever, lymphatic and splenic enlargement. Although with few exceptions the acute leukemia is of the lymphatic type, from the standpoint of the predominating cell, a glandular enlargement is by no means constant. Fussell, Jopson, and Taylor,⁹ report glandular enlargement in only 41% of the cases. McCrae,¹⁰ in a review of the cases in children, found glandular enlargement in 4 out of 13 cases; cervical glandular enlargement alone in 5; no enlargement in 2, and no reference in 2. Several writers, Hirschlaff,¹¹ Kormoczy,¹² Pappenheim,¹³ Meland,¹⁴ Dennig,¹⁵ Reed,¹⁶ have reported cases in adults without glandular enlargement. Certain groups of glands only may be involved, as in several cases the retroperitoneal or mediastinal glands have been very much enlarged, the superficial glands normal. In our case there was a very marked enlargement of the retroperitoneal glands, but only slight of the superficial groups. When only one group of superficial glands suffers it is usually the cervical. The enlarged glands are soft, not tender, and may show marked fluctuation in size; sometimes, at least temporarily, entirely disappearing. They do not tend to suppurate.

The spleen is palpable in about 65% of the cases and is usually only moderately enlarged thus differing from the chronic leukemia. The splenic tumor is generally of the acute type; in the few cases in which a very large hard spleen has been reported the question arises whether they are not cases of chronic leukemia with acute exacerbation. Absence of splenic tumor may be associated with normal lymphatic glands as in Dennig's case. Rupture of an acute leukemic spleen has never been reported until the present case; although in acute disease with enlarged spleen it is not infrequent, especially in malaria, as Playfair is reported to have seen 20 cases in 2½ years in the East Indies.

The thymus was enlarged in 15% of cases reviewed by Fussell, Jopson and Taylor, and in 1 case a mediastinal tumor is reported, its exact nature not being determined. The tonsils are quite uniformly enlarged and frequently the seat of necrotic processes. The liver is usually enlarged, chiefly the result of lymphoid infiltration.

Hemorrhage is a quite constant symptom present in about 70% of the cases, most frequently in the form of petechias or ecchymoses, but it may occur in any of the tissue or body cavities. Hematuria, hematemesis, epistaxis, hemorrhagic pleurisy, hemorrhage into the sheath of the facial nerve with consequent paralysis, retinal and cerebral hemorrhage, and a case with Ménière's symptom-complex from hemorrhage into the labyrinth have been reported.

Partly due to the subcutaneous or submucous hemor-

rhage, partly the result of lymphoid infiltration, necrosis is liable to occur. Necrosis and ulceration are chiefly confined to the digestive tract and are frequently the cause of hemorrhage from these parts. The mouth, on account of its liability to slight trauma and its abundant bacterial flora, is especially liable to necrotic foci. The stomach, and small and large intestine may also show extensive ulceration. Stewart¹⁷ reported ragged ulcers in the large intestine and appendix. Ulceration of the skin is infrequent and confined to those parts subject to pressure or exposed to trauma.

Fever is present in about 60% of the cases, is either of the continuous or septic type, and is usually of moderate degree, although a temperature of 103.5° F. has been reported. Secondary infection, especially in the mouth, is responsible probably for the temperature in many cases, in others no focus of secondary infection can be detected. The temperature may be present during the entire course of the disease, or develop only during the terminal stage.

The blood findings in this disease are characteristic and must always be the determining factor in the diagnosis. A leukocytosis is always present, as a rule not of such high degree as in the chronic type of the disease. McCrae reports 26,000; Dennig, 20,000; Müller,¹⁸ 6,800. These are cases with exceptionally low counts; as types of the other extreme are the cases of Kormoczy, 550,000; Pineles, 420,000; Müller, 350,000; Riernans, 362,000. Marked rapid fluctuation in the number of leukocytes is often observed. As in chronic leukemia, acute infections may cause a rapid reduction. In many cases a marked reduction occurs as the disease approaches its termination. Müller's patient, on January 30, had 109,600 leukocytes; February 1, 93,800; February 2, 46,000; February 3, just previous to death, 6,800. Fraenkel reports a reduction from 220,000 to 1,200 previous to death. In our case there was a marked increase before the fatal termination, which may have been due in part to a posthemorrhagic leukocytosis. The leukocytosis is in the majority of the cases due to an increase in the lymphocytes, and chiefly the large mononuclear cells. Strauss and Melland report cases in which extensive search failed to show a single granular cell. Of all cells present, 98% may be of large mononuclear type; these may be identical in appearance with the large lymphocytes in normal blood, others are larger and show a nucleus irregular and lobulated in outline. In a smaller percent of the cases the small mononuclear cells predominate: Fussell, Jopson, and Taylor, 88.8%; McCrae, 87%; Kuhnau, 85%. The eosinophile cells in the mononuclear type of acute leukemia are usually under 1%. Myelocytes may be absent, or at most only present in small number. Dennig reports a case in which within 6 weeks the character of the lymphocytes changed; in the beginning the large cells predominated; before death, the small cells. In Müller's case, referred to above, in which the leukocytes fell from 109,600 to 6,800, the large mononuclears predominated in the beginning; just before death the polymorphonuclear cells. Fraenkel, Müller, and Eisenlohr report cases in which during an acute infection the polymorphonuclear cells were increased until almost the normal percentage was reached.

In the past there has been some difference of opinion as to whether there was any form of acute leukemia except the lymphatic type. The blood-examinations in many of the reported cases are very incomplete, partly the result of inexperience and partly due to the work having been done before blood staining had reached its present high degree of perfection. Eichhorst reports a case in which the hematoxylin and eosin were employed, and in which the polymorphonuclear cells predominated. Others have reported large numbers of myelocytes present, many nongranular or with few granules. These are probably the same cells as others have looked upon as large mononuclear lymphocytes, although from their

appearance, the occasional presence of a granule, and their presence in the red marrow to the exclusion of almost all other cells, make it probable that there are bone-marrow cells which, as a result of imperfect formation or degeneration, are nongranular. Capps¹⁹ has recently reported a case of undoubted acute leukemia of the myelogenic type, and has collected several cases from the literature. The lymphatic type certainly predominates, but is not the only form of the disease.

Smears from the bone marrow in all the cases show almost complete absence of granular cells and the presence of a cell resembling in every respect the large mononuclear cell found in the circulating blood. These findings combined with not infrequent absence of lymphatic enlargement, support the recent tendency of pathologists to look upon all cases of leukemia of probable myelogenic origin.

The number of red corpuscles varies from almost normal to 1,000,000 depending largely upon the degree of hemorrhage. Other changes in the red corpuscle are dependent upon the degree of anemia. Nucleated cells, when present, are chiefly of normoblastic type, although in very rapid cases megaloblasts may predominate. The anemia is usually of secondary type the color index being low. In very rapid cases a high color index has been reported.

The chief diagnostic points are the hemorrhagic tendency, rapid anemia, fever, ulceration in the mouth, moderate glandular and splenic enlargement with the characteristic blood findings; and of all these the blood changes are most important and must be relied upon for the diagnosis. On account of the moderate leukocytosis which may exist in patients presenting the above symptom-complex, stained specimens should be made and a differential count will soon determine a marked disturbance of the normal proportion of various cells present or the appearance of myelocytes in large numbers if a leukemia exists. A failure to make a differential count has been responsible for the delayed diagnosis in many cases. Next in importance to the blood changes is the hemorrhagic tendency and mouth changes, and as these are found in other conditions, careful blood-examination should be made in patients presenting these symptoms. The following diseases are especially liable to be confounded with the acute leukemia.

Chronic Leukemia.—The blood changes may be identical. Onset gradual, no fever, slight hemorrhagic tendency, chronic course, enlarged glands if present, of greater consistency, hard splenic tumor. Acute exacerbation of chronic leukemia is much more difficult to differentiate as fever may be present and large mononuclear cells predominate. The history of the case and the nature of the splenic tumor are of great diagnostic value in these cases.

Purpura Haemorrhagica.—Moderate fever, splenic tumor not constant, joint pains often marked, glandular enlargement absent except in the neighborhood of infected ecchymoses. Inflammatory leukocytosis often present. Ewing²⁰ reports 56,000; Carrier and Gilbert²¹ 126,000, chiefly polymorphonuclear forms. Ewing speaks of an idiopathic purpura haemorrhagica without leukocytosis but with a large percent of lymphocytes (90% Engel, 80% Ehrlich, 75% Billings.)

Scurvy.—Splenic tumor occasionally present. History of insufficient or improper food. Glands only in neighborhood of infected ecchymoses, characteristic changes in mouth, the buccal mucous membrane escaping as a rule. Leukocytosis not constant and of inflammatory or posthemorrhagic type. Improvement under diet.

Pseudoleukemia.—Gradual onset; chronic course. A few cases of acute onset and rapid course have been reported. Enlargement of glands, higher degree, may be either soft or hard. Spleen large and firm. Slight tendency to hemorrhage or ulceration. Absence of fever, or if present, of "rückfall" type. Moderate, to

high degree of secondary anemia. Leukocytes may be diminished, normal or moderately increased, never however beyond the limits of inflammatory leukocytosis. At times relative lymphocytosis is reported. Several cases of pseudoleukemia which terminated as acute leukemia are reported.

Ulcerative Stomatitis.—Poorly nourished individuals. Process confined to gums. No subcutaneous hemorrhages. Local glandular swelling. Absence of or small splenic tumor. Inflammatory leukocytosis.

Sepsis.—More irregular fever with chills. Tendency to development of endocarditis, pericarditis, etc. Splenic tumor and often glandular swelling. May have tendency to hemorrhage. Finding of bacteria in blood. Absence of mouth changes. Inflammatory leukocytosis.

Our case resembled in many respects a tuberculous peritonitis, but the presence of general glandular swelling, hemorrhagic tendency, and blood changes allowed of a differentiation being readily made.

Course of the Disease.—With the single exception of a case reported by Mixa, the course of the disease is one of rapid and continuous progression to a fatal termination. In Mixa's case there was a remission of 3 weeks, during which time the symptoms all disappeared. The duration is from 4 days (Guttman²²) to 16 weeks (Fraenkel²³). The average duration of cases collected by Fussell, Jopson, and Taylor was 39 days. Litten would restrict the duration of acute leukemia to 6 weeks. But more important than the duration is the acuteness of onset and severity of symptoms, especially hemorrhages. Hemorrhage and complications as a result of secondary infection are the most frequent causes of death.

The various therapeutic measures employed in chronic leukemia and pseudoleukemia, arsenic, thyroid, bone-marrow, spermin transfusion, etc., have been employed without producing any appreciable change. The treatment must be directed toward the care of the mouth, prevention of bedsores, and protection from injury on account of danger of hemorrhage and ulceration.

DIPHTHERIA OF THE VAGINA WITH SECONDARY INVOLVEMENT OF THE MOUTH, RECTUM AND SKIN.

BY

THOMAS W. SALMON, M.D.

Assistant Surgeon, U. S. Public Health and Marine-Hospital Service.
Formerly Bacteriologist, New York State Hospitals.

This case, in which 3 uncommon forms of diphtheria existed, occurred during an epidemic at the Willard State Hospital. I am greatly indebted for the facts in the clinical history to Dr. Erving Holley, in whose charge the patient came, at the isolation hospital for diphtheria cases.

The patient, E. B., a married woman of 55, was admitted to the institution February 9, 1902, with acute melancholia. Her

physical condition was poor. She was thin and anemic and was also suffering from a mild attack of acute bronchitis. During the 6 weeks following her admission her health deteriorated.

As cases of diphtheria had occurred in the building in which she resided, she received an immunizing dose of 500 units of antitoxin March 4.

March 26, in the course of a gynecologic examination, 2 small, white patches were noticed on the labia minora and several near the meatus. There was no zone of inflammation about them and, as the patient presented none of the constitutional symptoms of diphtheria and her temperature was normal, the real nature of the patches was not suspected. On the same day that this examination was made she began to have diarrhea, and this continued until her death.

On March 27 the weakness accompanying the diarrhea obliged her to remain in bed, but on the following day she was up and about the ward.

April 2, in the course of the routine search for infected well persons, which was one of the measures employed in the management of the epidemic of diphtheria, a culture was taken from her throat and diphtheria bacilli were found.

April 3 she complained of a sore mouth and of pain in swallowing. An examination showed several discrete patches of membrane on the lips, the tongue, and the hard palate. A patch existed on the mucous lining of the cheek. Although she had no fever and no constitutional disturbance she was given 2,000 units of antitoxin and transferred to the isolation hospital.

April 4, a dense, white membrane was found, which completely covered the vulva to the mucocutaneous junction, the vagina, and the visible mucous membrane of the rectum. There was very little swelling and only a scanty seropurulent discharge. The membrane extended to the cervix the next day, but thereafter, until April 8, when there was considerable sloughing in the vagina, it neither increased in extent nor showed a tendency to become disintegrated. The membrane in the mouth extended to the tonsils. An abrasion on her left cheek which had existed before her admission to the isolation hospital became covered with a typical pseudomembrane which formed again after being forcibly detached.

When she was admitted to the isolation hospital she was greatly prostrated and it was then, 8 days after the appearance of the patches in the vagina, that her initial rise in temperature occurred. She experienced very little pain in the vagina and rectum, but complained bitterly when douches were given. Her mouth was intensely sore and swallowing was painful and difficult. The diarrhea, which had been only moderate before her admission to the isolation hospital, became profuse. The stools were small, watery, greenish in color, and offensive, but they contained no blood or mucus. Four days later shreds of membrane were present in the stools.

April 5. The patient's condition remained much the same. She took a fair amount of nourishment and the stools were a little less frequent.

April 6. There was no change in her condition. The diarrhea continued and no improvement followed the large doses of antitoxin which had been given.

During the next 2 days her prostration increased and the action of the heart became weak and irregular. Stimulation did not perceptibly improve it. She complained of great thirst and of nausea.

April 10. The patient's condition had become critical. There was no response to stimulation. Her exhaustion was increased by vomiting. Great thirst continued.

The patient lived through the following day in spite of increasing irregularity in the action of the heart. Thirst continued and everything but water was refused. There was no laryngeal stenosis, no evidences of bronchopneumonia and nothing to indicate inflammation of the uterus or the bladder. She died the next day, April 12, at 6 a. m. An autopsy was not permitted.

The patient's temperature on her admission to the isolation hospital was 102°. After that it only varied a fraction of a degree from 100°.

She received 21,000 units of antitoxin during the eight days preceding her death. A distinct reaction did not occur at any time.

The first culture was taken from her throat March 19, before she had shown any evidences of illness. No diphtheria bacilli were present. The next culture, April 2, was taken as a routine procedure and the presence of diphtheria bacilli revealed the true nature of the patches observed a week before upon the vulva. A culture taken from the throat the next day was negative, while diphtheria bacilli were present in nearly pure culture in one taken at the same time from one of the small patches of membrane on the lip. April 6, many barred and granular forms were present in the culture from the mouth. A culture from the vagina showed numerous very typical diphtheria bacilli resembling the forms present in the culture from the mouth. A culture from the rectum showed both diphtheria bacilli and streptococci, with many thick, evenly-stained bacilli. The diphtheria bacilli were very typical barred forms. April 7, a culture from the membrane present on the abrasion on the cheek showed many barred and solid diphtheria bacilli with streptococci. Cultures from the rectum showed both diphtheria bacilli and streptococci. Cultures taken the next day from the vagina, the rectum and the membrane on the cheek

all showed typical diphtheria bacilli. A nearly pure culture was obtained from the vagina, the types "A" and "D" of Webber predominating. A culture from the cervix April 9, contained fairly numerous diphtheria bacilli and many streptococci. The virulence of none of these cultures was tested by inoculating animals.

A Jacobi, in his "Treatise on Diphtheria," in 1880, reported several cases of diphtheria of the genitals but, writing in 1898, he said that these "do not bear perhaps the test of bacteriologic diagnosis."¹ It is exceedingly likely that this is true of most of the cases of diphtheria of the genitals and of wounds which were rather frequently mentioned some years ago. There is another test, however, and that is the occurrence of paralysis. The true nature of not a few of the cases reported before the days of bacteriologic examinations was revealed by the evidences of nerve degeneration which followed them. Marked improvement after the administration of antitoxin, in those cases in which a characteristic membrane accompanied the constitutional symptoms of diphtheria, must be regarded as very good proof of the nature of the disease.

During the last 10 years, cases of diphtheria of the male and female genitals have been reported from time to time in which the diagnosis was confirmed by cultures. In the brief abstracts which follow are included all the cases I was able to find in which the membrane present in the genitals was characteristic of diphtheria, or in which diphtheria bacilli were present in cultures.

The frequency with which this form of diphtheria occurs should not be estimated by the small number of cases collected in this summary, for doubtless others have been reported, and from the occasional mention of cases by physicians, it is certain that many which occur in private practice never find a place in the literature of the subject:

Coldstream² reported a case in a girl of 12. Her illness commenced with no local symptoms, but with a temperature of 102°. On the second day her temperature was 103°, and she complained of some pain in the genitals. The vulva was swollen, and there was a slight discharge. On the third day, 3 small, discrete patches of membrane appeared on the labia. Bleeding followed their removal. They disappeared on the sixth day, but a culture taken on the twelfth day showed the presence of diphtheria bacilli. No paralysis followed her recovery.

Biggs³ reported a case in a woman who was admitted to the Bellevue Hospital with alcoholic neuritis. Three days after her admission, the nurse noticed an offensive vaginal discharge, and an examination showed that the entire vagina was covered with a yellowish membrane, which extended to the internal os. There was no sloughing or ulceration. The constitutional symptoms were severe, her temperature reaching 105°. Her death, which occurred on the eleventh day after her admission, was preceded by a profuse diarrhea. The autopsy showed that the lower part of the rectum was the seat of a diphtheric membrane, but that the uterus and appendages were normal.

Bumm⁴ reported a case in which the entire vagina was covered with a dense, fibrinous membrane. He was so certain that it had resulted from streptococcus infection that he refused to administer antitoxin until the true nature of the case was shown by the presence of diphtheria bacilli in a culture.

Brinkmann⁵ reported 2 cases, both occurring in the puerperium. One of the women took a child who had diphtheria into bed with her on the third day after her confinement. Two days later her vagina and vulva were covered with a typical diphtheric membrane. Diphtheria bacilli were found in cultures from the throat of the child, but no cultures were taken from the mother. Both mother and child recovered after the use of antitoxin.

Brinkmann's second patient was delivered by a midwife. The woman got up 2 days after labor, but was compelled to return to bed because of high fever. A membrane was found in the vagina. The uterus and Douglas' pouch were exceedingly tender. The membrane disappeared the next day after antitoxin was used, but the fever continued, and she died on the fifteenth day after her confinement. Diphtheria bacilli were absent in cultures. This fact makes the diagnosis rather doubtful, even though improvement seemed to follow the use of antitoxin.

Nisot⁶ reported 2 cases in puerperal women in which membrane was present in the vagina and in the uterus, and in which typical diphtheria bacilli were found in cultures. Both were treated with antitoxin, and both recovered.

Munn⁷ reported 3 cases of diphtheria of the penis following circumcision. The first was in a boy, aged 5. Primary union had

taken place, but on the tenth day a grayish membrane covered the site of the wound. When the membrane was detached a bleeding surface was left, and a new membrane was speedily formed. There was considerable sloughing of the prepuce and brawny inflammation of the entire penis and scrotum. The constitutional symptoms were severe. On the sixteenth day after the operation the membrane disappeared, leaving a raw sore. No cultures were taken. No other cases of diphtheria occurred in the family.

The second case was in a baby of 9 months. The membrane appeared on the ninth day, and resembled that in the preceding case. Improvement followed the use of antitoxin, but in spite of a second injection, the membrane and ulceration extended across the perineum to the rectum, there was profuse hemorrhage from the bowel, and the child died.

Munn's third case was in a baby of 3 months. Three weeks after he was circumcised, his mother and a brother had diphtheria, the Klebs-Loeffler bacillus being found in cultures. A thin but typical membrane appeared on the child's prepuce, and cultures showed the presence of diphtheria bacilli. Two days later there were some tiny spots of membrane on the tonsils. There was no extension of the membrane on the prepuce, and in 3 days it had disappeared.

Williams⁸ reported a case following confinement, in a woman aged 20. She got up on the fifth day, and did well during the next week. On the twelfth day she had pain and a sensation of swelling in the vulva. On the fifteenth day the vulva was covered with a membrane. There was difficulty in urinating, and slight fever, with rapid pulse. No change occurred in her condition during the next week. A few days after she noticed the first symptoms, her 2 children became ill with diphtheria and died. Williams saw her on the eighth day after the appearance of membrane on the vulva, and found her suffering from little constitutional disturbance, and with normal temperature. Both labia majora and minora were covered with a grayish-white membrane, about 1.5 mm. in thickness. It was firmly adherent, and left a raw surface when detached. The vagina was normal. Cultures from the membrane showed diphtheria bacilli in nearly pure culture. Rapid improvement resulted from the use of antitoxin, and in 10 days all signs of the disease were gone. Several weeks later there was paralysis of both legs.

Courtney⁹ reported a case in a man of 47, in which pseudotubercles followed a suspicious ulceration of the penis. No cultures were taken, however, and as the condition persisted 6 weeks, and was succeeded by an exactly similar ulceration of a finger, which lasted the same length of time, the diagnosis may be regarded as somewhat doubtful.

Le Clerc¹⁰ reported 3 cases of diphtheria of the scrotum in which no membrane existed elsewhere. All the patients had the constitutional symptoms of diphtheria, and all recovered after the use of antitoxin. In one of the cases great sloughing, which necessitated a plastic operation, followed.

Coues¹¹ reported 2 cases of diphtheria of the vulva in children under 2 years. The membrane in each was very characteristic, and was on the labia majora. In one of them there was swelling of the vulva, and not in the other. One was primary and the other, which was fatal, was secondary to diphtheria of the pharynx. The author saw another case during the same year which led him to believe that the condition was not uncommon. The diagnosis in each was confirmed by cultures.

Gregory¹² reported a case in a young man in which a small patch of membrane appeared on the meatus. The first membrane was seen on the tonsils and uvula. It next extended to the nose, coming last on the penis. The constitutional symptoms of diphtheria were present, and rapid improvement followed the use of antitoxin. Some time after the membrane had disappeared cultures were taken from the nose and throat, but diphtheria bacilli were absent. No paralysis resulted.

Stahl¹³ reported a case of diphtheria of the uterus in a young woman. The perineum had been lacerated during labor and repaired. Fever, which reached 105° on the third day, followed, and the lochial discharge became offensive and watery, and contained yellowish membranous specks. The cervix was covered with a yellowish membrane and a culture taken from it showed the presence of diphtheria bacilli. The woman died on the eleventh day after delivery.

Ware¹⁴ reported a case in a child of 4. For 5 days before her admission urination had been accompanied by great pain and frequent stoppages, which led to the suspicion that stone might be the cause of the trouble. She had fever and accelerated pulse. The vulva was red and swollen. Three days after her admission 2 white patches appeared in the vulva—one on the nymphæ and one on the vestibule. Diphtheria bacilli were present in cultures. Paralysis of the fauces followed recovery, although there had been no membrane in the throat or in the nose.

Millard¹⁵ reported a case in which a membranous exudate appeared in the vagina and in the fauces during the third week of an attack of scarlet fever. The child recovered after the use of antitoxin, but as cultures showed only an abundant growth of *Staphylococcus pyogenes aureus*, it is doubtful if the condition was due to the diphtheria bacillus.

Mosler¹⁶ reported a case in a child, aged 10, who appeared at his clinic with membrane on the labia majora. There was, as in two of the preceding cases, great pain in urinating. Throat

symptoms appeared later, and the diagnosis was confirmed by cultures. A cousin, who was a playmate, had a similar condition at the same time.

Buccal diphtheria is somewhat rare, except in those severe cases of pharyngeal diphtheria in which the cheeks are involved by direct extension from the fauces.

I have been unable to find mention of a case in which membrane existed only in the rectum.

It is interesting to notice that of the 15 cases abstracted in which diphtheric membrane existed in the vagina or vulva, seven were in children and seven followed child-birth. It is a well-accepted fact that an abraded or abnormal mucous membrane is more frequently the seat of diphtheric membrane than a normal one, and it is difficult to conceive of any more vulnerable than the bruised and torn mucous membrane of the vagina after delivery.

The statement has been made that the uncommon manifestations of diphtheria have usually occurred in institutions, but, as a matter of fact, all but one of these cases (not including the one at the Willard State Hospital) occurred in private or dispensary practice.

The diagnosis of these conditions is of much importance, as they undoubtedly afford a greater opportunity for the spread of the disease than pharyngeal cases, and their insidious onset makes their early detection more difficult. The color of the membrane seems not to be always characteristic. The cases of Biggs and Stahl presented yellowish membranes, in the case at the Willard State Hospital it was pearly-white, and in several other of the cases reported it was the characteristic grayish-white, so familiar in cases of pharyngeal diphtheria. Swelling and discharge were not always present, and it is exceedingly important to know that a case so severe as to be followed by extensive paralysis could exist with normal temperature. As in doubtful exudates in the throat, culture taking is the one conclusive test and should always be employed.

The prognosis is apparently not more unfavorable when the membrane is limited to the genitals than in the more common forms of diphtheria. In 19 of the cases abstracted there can be no doubt of the diagnosis. Four of these patients died. One of the fatal cases was complicated with alcoholic neuritis, one was in a baby 9 months old, 1 patient was less than 2 years old, and one was a woman in the puerperium.

The treatment of such patients does not differ from that employed in ordinary cases of diphtheria. Antitoxin should be given in large doses at frequent intervals until convalescence is established. Local treatment can be carried out with greater satisfaction than when the pseudomembrane is in the throat. Irrigation with solutions of mercuric chlorid or carbolic acid may be used or, as Jacobi suggests, antiseptic ointments may be employed instead.

Unless carefully managed, these cases may be a prolific source of the spread of diphtheria. The urine and feces are almost certain to contain diphtheria bacilli and should be thoroughly disinfected. The vessels used by the patient, the bedding and the clothing should be regarded as infected and treated accordingly. A perineal pad or diaper of gauze impregnated with mercuric chlorid would serve to lessen somewhat the chance of infecting clothing. When one thinks of the possibility of a person who has recovered from diphtheria of the genitals distributing diphtheria bacilli on closet seats, on toilet-paper racks, and by means of the family wash for months after entire recovery, it seems reasonable to make an adequate number of negative cultures from the affected part an essential for the release of quarantine, or, when the objections to this cannot be overcome, to have the patient fully realize the necessity of the precautions which will suggest themselves.

THE DIAGNOSIS AND TREATMENT OF CONGENITAL MISPLACEMENT OF THE HIP IN INFANCY.*

BY

ALBERT H. FREIBERG, M.D.,

of Cincinnati, Ohio.

Professor of Orthopedic Surgery, University of Cincinnati.

Congenital dislocation of the hip has been made the subject of popular and professional discussion to such an extent within the past 2 years, that its recognition in typical cases and after the development of the limp is almost certain to occur. The general practitioner has indeed become so eager for the prompt treatment of these patients that in some instances his error has been made on the other side. The limp or waddle, so characteristic of typical and well-developed cases, has been made the principal or even the only diagnostic sign in the minds of many, so that in young children at least, rachitic bends of the femoral neck or even rachitic lordosis have been falsely looked upon as luxations. That these conditions frequently produce a limp very similar to that of luxation needs only to be known, their recognition then follows easily by considering the constitutional and local conditions.

A fact which is not so widely known as it should be, however, is that congenital luxation need not be accompanied by any but the slightest limp within the first 2½ years of life; that the shortening and ascent of the trochanter above Nélaton's line may at this time be so slight that in fat babies, particularly, they may be impossible of recognition by the ordinary clinical methods. General acquaintance with these facts has been prevented by two things. The notion that the luxation was primarily upward and backward as in the common traumatic form was the first of these. This has been disproved by Külliker, Hoffa, Schede, and others, who have shown that as a rule the primary movement of the femoral head is upward and outward, a direction more compatible with the indefinite physical signs to which I have referred. It was furthermore held by many, and for quite a time, that the replacement of these hips was not practicable before the children had acquired cleanly habits of person. This made it appear less necessary to recognize the existence of the abnormality before the end of the second year of life.

That with the advance of age and the exercise of the weight-bearing function of the limb, the difficulty of replacement increases greatly is acknowledged by all. The results reported by those most experienced, Lorenz, Schede, Mikulicz, and Wolff, show moreover that the proportion of anatomic cures after bloodless replacement is below 50%. This refers to such cases only in which a true replacement was supposed to have occurred. In a large part of those anatomic cures great abnormality of head or acetabulum must explain the failure.

It is doubted by no one that the abnormality in the shape and size of the head and acetabulum increases steadily during the period elapsing before reposition is accomplished. For these reasons the earliest possible replacement must be considered an important desideratum. Within the past 3 years it has also been shown clinically that in not a few cases children are born, not

with luxation of the hip, but only with the predisposition to it, consisting of disparity between the size and shape of femoral head and acetabulum respectively, or the abnormal development of either of these alone.

The examination of 150 radiograms in Hoffa's clinic of luxation cases, showed that in 25% of undoubted unilateral luxations, abnormalities were present in the supposedly normal hip, usually in the form of a too oblique acetabular roof or a socket which was too wide for the head. The importance of this observation is emphasized by the paper of Walter.¹ Of especial interest is the case of his own child. On account of a limp a radiogram was made at the age of 2½ years; this was believed to indicate rachitic coxa vara. Treatment by massage was followed by improvement. This was afterward lost, and a shortening of 1.5 cm. appeared. A radiogram taken at the age of 4½ years now showed distinctly beginning luxation. Two additional cases of similar character are reported by him in children of 2 and 3 years. A number of similar cases have been reported by Schede,² Heusner,³ and others. From these cases it would appear that in some instances at least, the head may remain in contact with the socket for a variable length of time even in the case of imperfectly developed joints. The greatest factor in breaking this contact must be the act of walking. It remains for us to determine in what manner and to what extent the existence of such conditions can be established, and having done this, to ascertain the practical value of such diagnosis.

In consideration of the fact that shortening of appreciable extent appears with the development of the weight-bearing function only, and that in a considerable proportion of cases head and acetabulum are in imperfect contact up to this time, it is unlikely that recognition of the deformity will be possible during the first year of life. The length of the limbs is practically equal under these circumstances. Vertical mobility of the femoral head of slight degree is frequently present in infancy for no better reason than laxity of capsule and amplitude of acetabulum. Measurements of children at this age are difficult, particularly as concerns the position of the trochanters. Bade⁴ has reported a case in which attention was attracted by the transverse creases in the skin on the mesial aspect of the thigh. Normally these are two in number—one above, near the adductor fold, and one lower down near the knee. When the child is placed supine with pelvis level and both knees firmly held in the same plane these creases should be symmetric. In Bade's case, and in the one presently to be reported, the crease was higher than on the normal side. I recently examined a child of 13 with unilateral luxation, whose mother declared without suggestion from me that she had observed this in her child during its infancy, and had even requested the physician to determine its cause. Naturally, 12 years ago such a request was not seriously entertained. The value of this sign has not yet been definitely established, and in bilateral cases would, of course, not avail; nevertheless, it should receive attention and should indicate further investigation.

Although the number of histories at my disposal is limited, I have been able to ascertain that in several cases children with congenital misplacement of the hip, have been late in walking. It is a common experience in mild grades of rachitis that children are late in walking. The usual age of 16 months is passed by and the rachitic child not only fails to walk, but is usually also unwilling to stand. I have been able to ascertain in several cases and to observe in one, that children with congenital luxation stand readily at the usual age for walking, and especially if allowed to support themselves by holding to some object. It is only when independent effort at ambulation is urged that the child shows its timidity, and refuses to make the attempt as a normal child will. This period is, of course, gone through by every normal child, but in some cases its long continu-

* Read before the Southern Surgical and Gynecological Association at Atlanta, Ga., December 15, 1903.

ance may be attributed to congenital luxation. The length of this period in luxation cases, too, varies greatly, but in every case is finally determined by the child's learning to walk with more or less limping, at which time the diagnosis is usually made and is of no further interest in this connection. In some few instances mothers observe these things, and possibly also that the apparent breadth of pelvis and perineum is unusually great. It is therefore urged that in the presence of any of these signs which have been referred to, attention be paid to the possibility of congenital luxation, and that in the event of any doubt the röntgen ray be resorted to as a final means of precision.

The question of the value of radiography in determining the condition of the hip-joints at this early age possesses considerable interest. In view of the fact that both femur and acetabulum are at this time largely made up of cartilage, a material casting but little shadow under the röntgen ray, it is not to be expected that an exact idea of the condition of the joint is given by radiography. Indeed, it is possible that in some

acetabular part of the joint, the shadow of the head appears normally separated from that of the socket about three-sixteenths of an inch. Under normal circumstances, a line drawn through the epiphyseal hiatus of both acetabulums, in the radiograms, will be tangent to the upper margin of the shadow of the femoral head. To determine definitely the relation of the head to the acetabulum it is necessary to photograph the joint both in internal and external rotation. The appearance of the iliac portion of the acetabulum is most important. Normally, this "roof" of the joint should be almost horizontal. In luxation cases it is invariably quite oblique. A slant of 45° is quite common, and it may be so oblique as to convey the impression that in the event of reduction the femur would find no purchase at all. This impression is, however, apt to be erroneous, since it ignores the existence of cartilaginous material sufficient to hold the femur in place, reduction having been accomplished. The value of the obliquity of the acetabular roof lies in its drawing attention to the malformation of the joint; valuable confirmatory evidence,

Fig. 1.—Before reposition.

Fig. 2.—After removal of first dressing.

instances our conclusions drawn from radiography alone would be entirely erroneous. This is shown by a case reported by Gourdon⁵ in which the skiagram appeared to indicate the absence of any articular connection between femur and pelvis, but in which by other means a normal joint was proved to exist. There is no doubt, however, that a satisfactory radiogram is the most certain means of recognizing congenital luxation in infancy, and if for any reason its existence is suspected, resort should be had to it. Radiography is naturally somewhat difficult at this age, as the cooperation of the child must be dispensed with. I have found this difficulty to be easily surmounted, however. Having arranged all details regarding the position of tube and plate, and the working of the apparatus, a few whiffs of ethyl chlorid or even chloroform will suffice to hold the little patient still. It is best to make 2 exposures to avoid the possible necessity of repeating this slightly disagreeable procedure.

In studying the radiograms of the hips of infants under 2 years, it must be remembered that the bony center of the femoral head is small in comparison with its cartilaginous covering. On this account, and also because of the large amount of cartilage composing the

especially at this age, and in the case of incomplete luxation.

In view of the foregoing considerations, it will be seen that valuable as is the radiogram in the diagnosis of luxation and subluxation, the appearances there found cannot be used with accuracy in determining the prognosis after reduction. This is to be drawn from the behavior of the joint under manipulation upon the operating-table; stability of reduction here argues for the success of the operation, and *vice versa*.

In discussing the treatment of malpositions of the hip in infants of under 2 years, it is not proposed to consider the technic of the operation or the subsequent plaster dressing. The proposition is simply advanced that experience has abundantly shown the feasibility of the procedure after the age of 1 year, and that the results amply justify the great additional care which is necessary to prevent the dressings from becoming soiled, in patients so young. Differing in no essential detail from the operation upon children a year older, the maneuver is likely to astonish one by the ease with which reduction is accomplished and by the stability of the femur in its new position even when the limb is adducted.

Tracings from radiograms of a case before and after

reduction are offered in evidence of the statements just made.

The child, a girl, was brought for examination at the age of 17 months, because it would make no attempt to walk. The child was unusually heavy, but from its birth perfectly healthy. It was born after a perfectly normal pregnancy and labor, the latter requiring no assisting manipulation whatever. At the end of the first year the child began to stand with support, but could not be made to attempt walking, up to the time I was consulted. At this time the child's physical condition seemed perfect with the exception of the left lower extremity, which appeared something less than $\frac{1}{2}$ inch shorter than the right. There seemed to be slight vertical motion in the left hip, but not in the right. The position of the trochanter and the relation of the femoral head to the femoral artery could not be made out on account of the great amount of fat. The radiogram (Fig. 1) showed defective formation of the acetabulum, a capital epiphysis smaller than on the right side and situated upward and outward from the normal position.

The reposition was exceedingly easy and occurred with a snap so violent that the onlookers thought the femur must have been broken. In the ease and stability of reposition it was like a traumatic luxation. The plaster dressing was applied in the usual manner especial care being taken to protect the plaster by draw towels and rubber protective. The recovery was uneventful and the child made its first attempts at walking 3 weeks after operation. Ten weeks after this the child was chloroformed after removal of the plaster and a radiogram made without disturbing the position of the limb. Figure 2 is a tracing made from this and shows, I believe, a perfectly satisfactory position. The second plaster dressing was applied after reducing the abduction more than half.

It is as yet too early to speak of the ultimate result in this case and it is offered only as evidence of the ease and stability of reduction when done early, and the feasibility of maintaining it in very young children. It seems, moreover, fair to presume that if in this case another year had been allowed to elapse without reposition the difficulty of accomplishing it would have been greatly increased. It is more than possible that in this time, also, alterations in both hard and soft parts would have occurred sufficient to render an anatomic cure impossible.

Having discovered that imperfect formation of the hip-joint exists before the contact of femur and acetabulum has been markedly disturbed it should be possible to prevent the further progress of luxation and to favor the development of a secure joint. This would be accomplished by maintaining the limb in decided abduction, say of 25° , during the act of walking. The plaster spica worn for a period of about 6 months in this position should rightfully be considered the best means of attaining this end. A brace might doubtless be made to act similarly though with less certainty and constancy.

NOTE.—Since the foregoing was written, the last plaster dressing has been removed from this patient. The radiogram shows a perfectly satisfactory position of the femur. The acetabulum has developed considerably so that the difference in slant of the joint roof of the two sides is now only 10 degrees. The limbs are now of equal length and the child walks without the slightest limp.

Smoke Ordinance Reported.—After more than a year of discussion, Councils' Committee on Boiler Inspection has agreed to report favorably an ordinance to mitigate the smoke nuisance. According to the terms of the bill, 2 color scales are to be the standards for the density of smoke to be permitted at various establishments, but between 4 and 7 o'clock in the morning there is to be no restriction. Another exception to the general requirements is in the case of locomotives and river craft, in continuous transit through or across the city, or entering into or departing therefrom. No fumes of obnoxious odor are to be permitted to escape from any foundry or furnace within the built-up section of the city. A penalty of \$25 for violation of the terms of the ordinance is provided.

AN ORIGINAL OPERATION FOR COMPLETE LACERATION OF THE FEMALE PERINEUM.¹

BY

C. E. RISTINE, M.D.,

of Knoxville, Tenn.

On February 20, 1897, in an operation upon a female patient for complete laceration of the perineum, I devised and carried into effect a procedure with such a degree of success that I reported the case in detail in a paper read before the Knox County Medical Society at its stated meeting, May 11, 1897. Later, upon invitation, I sent an article for publication to *The American Journal of Obstetrics and Diseases of Women and Children*, describing the various steps in the operation. The publishers very kindly reproduced some pencil sketches I made which, although not perfect, illustrate the procedure very well (see March number, 1900).

The basic principle of this operation is inverting into the rectum a frill of mucous and cicatricial tissue which is dissected from the vagina. In describing the successive steps of the operation I shall quote freely from my original and also my published article.

1. An outline incision is made which varies in shape and length to conform somewhat to the extent of the laceration, with special reference to the rectal tear. If the laceration extends up the vagina into the sulci, I begin the outline incision above the apex of said tear, making sure to have an abundance of tissue, so that when dissected off as far as the apex of the rectovaginal tear and inverted into the rectum, it will reach well below the anal orifice. From this initial point I direct the outline incisions outward and downward to points I have selected for the lower border of the future vulva and upper border of the perineum, then extending the incisions down from this point on a line with the torn edge of the perineum to the outside of the pits marking the retracted ends of the sphincter ani muscle.

2. Following the outline incision, I begin denuding the mucous membrane and cicatricial tissue included in the outline from the highest point in the vagina, and carefully dissect—without buttonholing—down to the apex of the rectal tear, and laterally from the incisions down to the margin of the rectal tear, being particular not to disturb its connection here. These lateral incisions should expose the ends of the sphincter muscle.

3. Now invert the frill into the rectum, and draw it well down below the anal margin with tissue forceps, which should be left attached for further traction if required when adjusting vaginal or perineal sutures.

4. At this stage of the operation, draw out and freshen the ends of the sphincter muscle, through which pass a chromicized or cumolized catgut suture near its ends; gentle traction on this suture will approximate, but will not place the ends in apposition; now, while the traction is continued, pass a silkwormgut suture back of the catgut suture through skin and muscle, taking a deeper hold of the muscle; when traction is made on this reinforcing suture, the ends of the sphincter can be brought in contact. This suture also passes through the frill between the dissected surface and the mucous membrane, for the purpose of preventing the frill from retracting above the anal margin. Those sutures passed first are tied last.

The remaining steps in the operation are the same as those in incomplete laceration, and require no further description, as we have practically converted a complete into an incomplete tear.

The advantages of this operation over all others for this purpose are obvious. The rectum is shut off completely from the denuded area by the inverted frill, with its mucous surface forming the anterior wall of this organ, giving an unbroken rectal mucous lining. There are no stitches in the rectum to carry infection, or requiring removal. The frill supplies tissue to the rectum that has been destroyed by sloughing, retraction, and atrophy.

In my published article describing this operation, I make mention of 3 patients successfully operated upon, since which time I have had only 1 case of this nature, and I operated upon this patient in 1902 with satisfactory result.

In my first case I used silkwormgut and silver wire for vaginal and perineal sutures, which for some cause tore out on the third day; on the following day I

¹ Read before the Knox County Medical Society, October 29, 1903.

removed all stitches, freshened the denuded area with a sharp curet, reintroduced sutures, catgut for the vagina and silkwormgut for the perineum, with a successful result.

I do not use a dressing of any nature over the sutured area, the nurse is instructed to throw a stream of mercuric chlorid solution (1-2,000) over the labia after urination whether the act be accomplished with or without the aid of a catheter. After the lapse of 5 or 6 days a vaginal douche is given every 24 hours, using some mild antiseptic such as boric acid or normal salt solution. As soon after the operation as the patient's stomach will tolerate it, I order the administration of a tablespoonful of compound liquorice powder in a half or two-thirds of a tumbler of water, and repeat it often enough to insure 2 soft free actions from the bowels every 24 hours. The diet should be limited to such articles as furnish the greatest amount of nourishment with the smallest amount of fecal matter. Failing to appreciate the necessity of tying the legs together, as most of the textbooks tell us, I allow free use of the limbs while in the recumbent position, as there is absolutely no motion made by the leg or thigh which will in any manner disturb the recently adjusted parts. I do not use a self-retaining catheter for good reasons. The perineal stitches of silkwormgut are not removed until after the eighth day.

Since the publication of my paper in 1900, this operation has been performed by some of our best surgeons in the larger cities with such gratifying success that they pronounce it ideal.

Dr. E. E. Montgomery, Professor of Gynecology, Jefferson Medical College, Philadelphia, has done me the honor of mentioning my operation in his very excellent textbook, "Practical Gynecology," second edition, 1903.

ENURESIS.*

BY

GEORGE E. BEILBY, M.D.,

of Rochester, N. Y.

Resident Physician, State Industrial School, Rochester, N. Y.

Although this is a subject which has received the attention of the profession for generations and upon which much has been written, yet one has only to look over the literature and textbooks and note the vaunted nostrums and specifics, all of which are equally worthless, to realize fully that the treatment of enuresis is oftentimes very disappointing and the underlying etiologic factors in many cases not clearly determined. Enuresis is usually considered a disease of childhood proper, most common between the third and tenth years of life and affecting both sexes about equally. But, I think you will agree with me that often the largest number of cases is seen among the adolescent in asylums and institutions, where they are gathered in large numbers, and that these are the cases which present the greatest difficulties in management, and that the majority of such cases occur among males.

It is of this institution variety that I wish to speak in this paper, as my observations have all been made during the last 3 years at the State Industrial School in Rochester, an institution receiving children of both sexes between the ages of 10 and 21 years, committed from all types of society, from the best to the degraded and degenerate. We have a population varying from 800 to 900, of which about 100 are girls. Of this entire number my records of these cases taken from month to month show variously from 30 to 70 or 80 cases of enuresis, or 4% to 10% of the population. Other similar institutions report even a larger percentage, 18 to 20 in one instance. Compared with children of like ages under normal conditions, that is, outside of institutions,

the proportion is extremely high, and here arises the question: How can we account for this vast difference? Let us first consider the potent causes of enuresis, and here we will eliminate those cases due to malformation of the genital tract and those caused by organic diseases of the central nervous system as not applying in this paper and simply consider the ordinary form of childhood which is usually termed a neurosis.

In infancy the act of micturition is simply a reflex involuntary one. An impulse is sent up from the nerves of the bladder to the lumbar center which produces simultaneously a relaxation of the sphincter and a contraction of the other muscles of the bladder, expelling its contents. Normally, after the second or third year, cerebral control is exercised over this center. Incontinence therefore may be due to (1) lack of development of the cerebral center and continuance of the infantile condition; (2) to irritability of the terminal nerve filaments in the bladder or surrounding parts; (3) to irritability of the spinal center.

Out of a total of about 250 cases, the entire number in the institution in 3 years, I have had under treatment in our hospital 75 patients, and have kept complete histories and records of their cases. They were in no way selected, excepting that they were those in which the condition was the most pronounced, and to which my attention was called from time to time. But 2 of these patients were imbeciles, and in only 7 were there well-marked physical signs of degeneracy, though many were the offspring of more or less defective parentage. Thus it is fair to suppose that in 73 of the cases there was no lack of cerebral control. Examination of the urine never revealed marked abnormalities, nor were there signs of vesical calculus or rectal irritation, and in only a few of the cases sufficient phimosis to cause the condition. So that, with the exception of these few cases, I believe none could be assigned to this category, which is commonly believed to be one of the most frequent causes of enuresis. By exclusion, therefore, we arrive at the third cause, irritability of the spinal center, by which to explain the majority of the cases. The histories might be summarized as follows: Seventy-one were in males, 4 in females. The ages ranged from 10 to 21 years: 1, 10 years; 6, 11 years; 14 each 12 and 13 years; 16, 14 years; 11, 15 years; 4, 16; 5, 17; 3, 18; and 1, 21 years. Sixty suffered from nocturnal enuresis only, 2 from diurnal only, while 13 were both nocturnal and diurnal, and 6 had incontinence of feces, as well as urine. As regards the length of time which the condition had existed, it varied from a few weeks or months to several years, or perhaps as long as the patient could remember, and some were of such moderate severity that they only wet the beds now and then a night, while others would invariably do so two or three times. Many of these patients were known to be chronic and excessive masturbators. By careful questioning and close observation, a positive history of such habit was determined in 71 of the cases, leaving only four doubtful. Some were very reluctant in admitting the practice, and might deny it absolutely. These were carefully watched by night-guards, and almost invariably our suspicions were corroborated. It is surprising to what excess and for what length of time it was practised in many cases. For instance, one lad of 13 stated that for 2 or 3 years he had practised the act once or twice every night, and sometimes days also. Once a night, or every other night, is about the average, and extending over periods of 2, 3, and even 5 or 6 years, if they were truthful in giving their histories. These cases clearly showed a direct ratio between cause and effect, the worst cases of self-abuse being the most troublesome ones of enuresis.

As to the *modus operandi*, there may be some difference of opinion. But in these cases I think it is clearly demonstrated, as I shall show later, that there existed a hyperexcitability or hypersensitiveness of the center for

* Read before the annual meeting of the Medical Society of the State of New York, Albany, N. Y., January 26, 27, and 28, 1904.

erection in the cord, caused by repeated and prolonged stimulation, and that this condition, whether it amounted to an actual congestion or not, extended to the adjacent centers of micturition and defecation, and that the same condition obtained here. While the exact location of these centers has, I believe, never been clearly determined, yet most authorities, as Halliburton,¹ Starr,² Howell,³ and Peterson,⁴ all place them in the lumbar enlargement of the cord, also the center for ejaculation. I am not prepared to state that the abnormal condition present in these reflex centers in the lumbar cord is an actual congestion, but that such might be the case seems very probable. To quote from Gowers,⁵ "An active congestion which may be termed secondary, seems to result from prolonged and violent action of the nerve elements of the spinal cord. Thus local dilation and distention of vessels, migration of leukocytes into the sheath and into the adjacent tissue, and even small extravasations, are found in some cases of hydrophobia, tetanus, and of strychnin poisoning, and it is probable that a similar congestion attends all violent physiologic activity, violent and continued muscular exertion, coitus, etc. Coitus several times repeated has been known to cause hemorrhage within the cord, which must be preceded by an intense congestion. Vascular dilation with an increased blood supply is the physiologic attendant of functional activity in all organs, and doubtless also in the cord, but is morbid only when excessive."

That in these cases this condition of enuresis is due to an irritation of the reflex center rather than to a peripheral irritation seems to be clearly borne out by certain very interesting phenomena which only recently have come to my attention in the examination of these cases, and which seem to indicate, moreover, that this irritative or congestive condition extends further, and involves other reflex centers in the lumbar cord; that is, the cremasteric gluteal and tendon-reflexes of the lower extremities, as shown by the result of the examination of 25 of the recent cases, or a third of this series.

The first symptom which attracted attention was the frequent complaint of a dull aching or an actual pain referred to the lower dorsal or lumbar region and the presence of tenderness on palpation. This symptom of tenderness was present in 10 cases, very marked in 3, and absent in 12, the exact location being most frequently over the second, third or fourth lumbar vertebrae, and extending out over the nerve endings of the posterior division of the spinal nerves arising from these regions.

Examination of the reflexes gave the following results:

Cremasteric.—This was found to be greatly exaggerated in 9, exaggerated in 8, brisk in 4, and normal in 4.

Patellar, greatly exaggerated in 11, exaggerated in 7, brisk in 4, and normal in 3.

Gluteal, greatly exaggerated in none, exaggerated in 3, brisk in 2, and normal in 20.

Achilles, greatly exaggerated in 3, exaggerated in 13, and normal in 9. Tendency to ankle-clonus of short duration in 2 cases.

Plantar reflex normal in 12, diminished in 13.

Upper Extremities.—(a) Triceps, greatly exaggerated in none, exaggerated in 2, brisk in 7, normal in 9, and sluggish in 8. (b) Biceps, greatly exaggerated in none, exaggerated in 2, brisk in 4, normal in 9, and sluggish in 10.

Wrist.—(a) Flexors exaggerated in 1, perceptible in 7, not perceptible in 17. (b) Extensors exaggerated in 1, perceptible in 3, not perceptible in 21.

In making these tests I was assisted by Dr. Robert G. Cook, so that there can be no doubt as to their accuracy.

Here is the condition. How, if not in the manner indicated, can it be explained? An almost uniform exaggeration of the muscular and tendon-reflexes of the lower extremities, together with the bladder and rectal

symptoms, with no exaggeration of the reflexes of the upper extremities, with the exception of 2 cases. In one of the latter the condition of incontinence was very slight, and yet all the reflexes of both upper and lower extremities were very greatly exaggerated and the tendency to ankle-clonus was present. I can offer no explanation in this case. The other lad was decidedly a psychoneurotic, and this might account for the condition of his reflexes. It might be asked if all these cases did not exhibit the so-called neuropathic taint. This was true in only 1 out of the 25 cases, which is the case already mentioned. None of the others exhibited and of the "stigmata" of hysteria or neurasthenia, any in only three were marked physical signs of degeneracy.

Very little literature has been available on this subject. Jacobi,⁶ as long ago as 1876, called the attention of the profession to masturbation as being a very frequent cause of enuresis, and again in 1890, in "Keating's Cyclopaedia of Diseases of Children," he states his belief that it is a more common cause than is generally considered (and that it is due to the constant irritation of the prostatic portion of the urethra and neck of the bladder by frequent erections). This may be the explanation in some instances, but in my series of cases it would seem very positive that there existed an abnormal increase of irritability in the lumbar enlargement of the cord, which would account for the exaggerated condition of the reflexes of the lower extremities, as well as the incontinence of urine and feces. Prendergast⁷ reports 80 cases of enuresis in an orphanage, out of a total population of 485, the ages ranging from 6 to 12 years. He, excluding idiocy and imbecility and the general neurotic state, is inclined toward the belief that it is "downright laziness" in the majority of cases which causes the condition. I should hesitate in accepting this as a cause in so large a number of cases, and especially when restricted diet and punishment did not tend to correct the condition. Of the 80 cases, he reports 75 cures, and improvement in the remaining 5, during 8 months of treatment with cold spinal douching. The success of his treatment I should attribute not alone to the strong mental impression caused by the cold douche, but to its tonic and sedative effect upon the reflex centers in the lumbar cord.

Proof may be lacking in some instances, but it is my earnest belief that at least 90% of all cases of enuresis occurring among the youth and adolescent in institutions are caused by self-abuse. The class of children gathered in asylums and institutions is very prone to indulge in this habit, but it is the direct teaching one to another that gives us our large number of cases. It has been my experience that the great majority of boys coming from orphan asylums and houses of shelter are addicted to the practice of self-abuse, and a certain percentage of these always suffer from incontinence. Seclusion, intimate association, and lack of diversion in mind and bodies weakened by ancestral immorality, offer a ready explanation. I might mention in this connection that 20 of my 75 patients had previously lived in asylums or institutions.

Treatment in these cases is usually attended with good results, if the condition is not of too long standing. It should be directed along two lines: First, by appealing to the moral sense and warning the child of the dangers of evil practices. Second, by improving the physical condition and attempting to relieve the congestive or irritative condition of the lumbar cord. Circumcision was performed in these cases, almost as a routine, not because there was a phimosis, for as I have said in only a few cases was this condition present, but for its mental impression alone, in tending to prevent the practice of masturbation, and this I consider a very important feature in the treatment. At times also it will be necessary to follow this by electricity, cold spinal douching or counterirritants over the region of the lumbar cord.

Then the systemic and nerve tonics are indicated, and antispasmodics, of which bromid and belladonna excel.

Following out these general lines of treatment, improvement or what seems to be in many cases a cure, results; but the fact remains that the habit of self-abuse has become so firmly grounded that, unless every case is followed up with considerable earnestness, they drift back to their former condition.

SIX MONTHS' WORK IN A DISPENSARY FOR DISEASES OF THE LUNGS.

BY

THOMAS H. A. STITES, M.D.,

of Scranton, Pa.

The "Free Dispensary for Diseases of the Lungs" was opened for work under the auspices of the Scranton Society for the Prevention and Cure of Consumption, on January 1, 1903, by Drs. J. M. Wainwright and L. B. Woodcock, who were succeeded on July 1, 1903, by Dr. William F. Bennett and myself, and it is of the methods pursued and the patients treated subsequent to the latter date that I intend to speak. We found the dispensary stocked with a small, but very serviceable, supply of drugs principally in tablet form; a sufficient number of cardboard sputum cups for supplying every case in which they were needed; a few instruments for examination of nose and throat; a considerable amount of reading matter for the guidance and information of patients and their friends, and tickets for milk to be distributed to those too poor to pay for that article so important in the diet of the tuberculous. Our methods were simple, and, as was to be expected, the simpler the more successful. After obtaining the social and personal history of each applicant as thoroughly as possible, a thorough physical examination was made of heart and lungs. We then entered upon the treatment indicated by history and examination, which, in the majority of cases, consisted of a tonic tablet of iron, quinin, and strychnin; frequently a sedative expectorant tablet of terpin hydrate and heroin; at times a bronchitis mixture of Dover's powder, ipecac, belladonna, and quinin in tablet form. In many cases dyspnea seemed the most troublesome symptom, and was dealt with very satisfactorily with what we called "emphysema mixture," which consisted of a small amount of morphin, some potassium iodid, tincture of belladonna, and Hoffman's anodyne in syrup of wild cherry. A dose of this mixture given 3 times a day produced some very happy results. In cases in which gastrointestinal disturbances were manifest we found a tablet of pepsin and pancreatin moderately successful. When constipation existed, we dispensed a compound aloin and cascara tablet which so far as reported never failed to relieve. In cases in which there were throat complications we dispensed a gargle of one of the creasote preparations. At times when more powerful expectorants were called for we had recourse to the old ammonium chlorid and brown mixture tablet, which we found of great value, especially when followed by small doses of heroin or codein. When special symptoms demanded drugs outside this list, prescriptions were given, and in worthy cases these were filled at the expense of the society; probably the most frequent prescription being for atropin to control the night-sweats. Each patient was carefully instructed as to the great—indeed, the absolute—necessity of being in the open air as much as possible, some were even persuaded

to swing hammocks and sleep there. The diet was not neglected, and the articles most advised were eggs, milk, and meat—especially the first. Stress was laid upon the danger of infection of other members of the household and the community at large. Paper sputum cups were furnished and their use explained, and patients were told that a new supply could be obtained at any time. Advice was given concerning the disposition and care of bedding, clothing, handkerchiefs, table furniture, etc., and the importance of care was emphasized at every opportunity, both verbally and by means of the printed pamphlets supplied by the society, and distributed to every patient. We deemed this distribution of information quite as much one of our objects as the treatment of patients. When it seemed advisable the society's visiting nurse was notified, and she called at the houses of the patients to help as best she could. In some of the cases which came under my observation the services of this nurse were of the greatest value.

When late in the summer the society opened its West Mountain Sanatorium, patients whose cases proved to be tuberculosis, and who were not too far advanced, were urged to apply for treatment there, and a falling off in the attendance of such patients at the dispensary was at once noticed. Many, however, seemed to fear the open-air life at the sanatorium, and it was with no little urging that some of them were persuaded to apply; some few persisted in their refusal despite all that could be said. It was interesting to note the incredulity upon the faces of some when we told them that a widely opened window in their bed-rooms would be of great value, and some, I fear, set us down as cranks and unworthy of confidence.

Our results in the pulmonary cases were, considering the lack of control over our patients, very satisfactory. We are not ready to claim any cures, for it seems to us that the period of time covered is altogether too brief to permit of any such claim, but we do claim—and our case histories support the assertion—that many patients were markedly benefited; some, we have reason to hope, permanently, and that few applied to us who did not obtain great relief.

Altogether, during the 6 months, we admitted 72 new patients; of these 47 had pulmonary complaints, and of these at least 26 were tuberculous. The remaining cases were diagnosed as bronchitis, subacute and chronic; and in a number of these it was impossible to eliminate entirely the suspicion of tuberculosis. Eight cases proved to be endocarditis, and the remainder were of various complaints—catarrh, tonsillitis, adenoids, laryngitis, syphilis, cystitis, and neurasthenia.

To consider more particularly the tuberculous cases—it was wonderful to observe the almost immediate improvement, the gain in weight, the lessened dyspnea, the alleviation of cough, the gain in strength, in some cases the return of a healthy color to the cheeks, which followed the observance of our advice and the use of the simple preparations we dispensed. To the best of our ability we strove to enforce upon each patient the fact that his or her case was not hopeless—that the danger was great we never denied—and that the patient was engaged in a hard, long, tedious fight for life, for health, and for strength, in which we, the physicians, could only guide and direct; that the work was not for us to accomplish, but for the patient, while we were always at hand with medicine or advice. In most patients this seemed to breed a fighting mood, and a sense of responsibility, and a readiness to follow advice; and it is to this mood and the cheerfulness that comes with it that I ascribe much of the favorable result of our treatment. Some there were who declined to help themselves, and with these we had difficulty, but after persuading them to try our methods a little gain was noted, and usually that was sufficient inducement to continue the fight with more courage. Unfortunately, as is so often the case

with the tuberculous, the improvement, remarkable as it seemed, was in a number of instances but temporary, and it must be confessed that our efforts served but to stay for a time the inroads of the disease, and that death will, after a shorter or longer period, end the fight. Still it is something even to check such a course, and to have given relief to suffering. Further, there were cases, some of them pronounced, in which the patient's condition was far better after 6 months than it was when they first applied to us for help. Several showed by examination marked improvement, and in these the subjective symptoms had almost disappeared, and one cannot but feel that a process of real improvement had been begun. The case of a boy of 9, admitted a few days before we took charge, and who was seen at intervals during the whole 6 months, is worthy of remark. There were rales and dulness all over one apex, there was history of a cough, of progressive loss of flesh, strength, and spirits, little appetite; in fact, fully enough to give base for diagnosis, despite the lack of bacteriologic confirmation—due to the persistent refusal of the boy to collect sputum for us to examine. We instituted at once a regime of outdoor exercise, nutritious food, a tonic, the iron, quinin, and strychnin before mentioned, and at once there began to be manifest a gradual improvement, which continued steadily, until at the final examination, just before handing over the work to our successors, we could find no abnormality of the percussion note of either side, there were no rales to be distinguished even with the aid of such instruments as the phonendoscope and Bowles' stethoscope; the cough had entirely disappeared, while the father positively complained of the boy's appetite. He was strong, and stouter than most boys of his age. Of course, it must be admitted that the lack of bacteriologic confirmation of the diagnosis leaves an element of doubt in this case, but the signs were very positive, and sufficient for a diagnosis. In reviewing the 6 months' work, one cannot help wondering whether in selected cases, in which the patient can and will cooperate in the fight, the home is not as good a place for treatment as a sanatorium or hospital; at all events, it is worth trial. Another lesson borne in upon us is the fact that the less expensive remedies are of great value, for in the operation of a charity such as this, having slender resources, it was important to avoid, so far as possible, the use of expensive preparations.

A discouraging feature was the fact that so many patients disappeared from observation before we could come to any decision as to the success of our efforts. Some went to our own sanatorium, some to other institutions, some were lost to sight entirely. The patients admitted to the West Mountain Sanatorium are reported doing well.

Consideration of the occupation of the patients suffering from pulmonary and cardiac complaints reveals at once the predominance of those which expose the individual to dust. Of the 55 cases we find that 17 were in women engaged in the duties of their homes. Twelve were in men connected with the mines. Six were in people employed about machinery. Among the remaining 20 patients we find 2 were clerks, 2 bakers, 3 carpenters, 5 school-children, a mason, a plasterer, a hatter, a mill hand, a butcher, a governess, and a seamstress. In a large proportion of the tuberculous the family history was negative. It is rather startling to find such a large percentage among those most liable to convey contagion to their families, the women engaged in household duties. It was to them that we gave the most careful instructions as to how to care for the safety of their families and associates.

One handicap under which we have labored incident to this class of work and which it is feared can hardly be avoided, is the fact that most of the patients applying for treatment do so only after the disease has obtained a firm hold upon them. A very frequent statement was that there had been a cough growing more and

more severe for a period seldom less than 6 months, frequently 2 years, and in 1 or 2 cases as long as 6 years. It seems to me that while avoiding so far as possible all unnecessary alarms and "yellow journal" methods, a continual effort must be made to influence people to seek early treatment for coughs and cold. One cannot help believing after seeing the immediate and marked benefit of treatment in even the advanced cases that the same care and methods instituted early would have wonderful results—results every whit as favorable as those claimed by the extreme advocates of the treatment. It is not an easy thing to tell a patient, the mother of a family of young children, or the father upon whose labor depends their support, that he or she is in the toils, and that the outlook is bad; it is not an easy thing to tell such a one that there is even a suspicion of the disease; but it is a heart-breaking thing to be forced, in answer to the question, spoken or unspoken, to say that there is not much hope. For my part, I prefer to start an alarm a bit earlier than that, even to give an occasional unnecessary alarm, while I can still tell my patient that the chances are in favor of a cure. In most of the cases that have fallen to my lot it has seemed best to practise frankness, to tell the patient the truth without exaggeration, and at the same time hold out hope to nerve him or her to the fight. The mental condition has a great effect upon the physical condition, and a fighting spirit once raised is of no little assistance. It has been my constant effort to combine conservatism and truth, and thus far experience has confirmed my allegiance to such a course.

Another thing which struck us forcibly was the percentage of patients applying who were proved beyond doubt to be tuberculous. Our patients were drawn from the poorest class of a population of a little over 100,000, in a vicinity noted for its healthfulness. Yet out of 72 patients admitted to treatment 26 were found tuberculous, and the diagnosis was founded not alone upon physical signs but in at least 24 cases upon the evidence of the microscope as well. Many have been inclined to ridicule and decry as exaggeration the warnings and statements of the tuberculosis agitators, but here is some actual, tangible proof of the existence of a number of such cases, an exhibit which is the more remarkable when it is remembered that we did not in any way encounter those who apply to their own physicians for aid and advice. It is a startling revelation of disease, and were the work of our dispensary but one of warning and education it seems to me that its existence has been more than justified. Scranton and its vicinity is no exception to the general condition of all urban and suburban localities, indeed in many respects conditions here are better than the average, and it is an encouraging sign that at least two other cities of this State, Pittsburgh and Wilkesbarre, are joining the crusade, while Philadelphia is already deep in the fight.

I do not think that the abuses of our dispensary have been such as to interfere seriously with the prosperity of any practitioner and we have been able to relieve materially much distress, and to distribute information which we believe will tend to protect many from infection by the tubercle bacillus.

Adulterated Foods.—A very large proportion of the lemon extracts offered for sale are inferior products containing but little lemon oil. Many brands contain no lemon oil whatever and are but weak alcoholic solutions, colored with coal-tar dyes and having but a suggestion of the flavor of lemon. Of the 10 brands examined, 7 were fraudulent in character and but 3 contained the required 5% of lemon oil. The manufacturer of one of these high-grade extracts went to the unnecessary expense of coloring his product with anilin dye and thus adulterating what was otherwise an excellent article. The 4 brands of sausage examined have all contained boric acid. One of these brands was supplied by the manufacturer, who supposed it to be pure. It appeared that he was using a "sausage filler," consisting largely of starch, for rendering the sausage less fat. Upon analysis this sausage filler was found to contain considerable boric acid.—[*N. H. Sanitary Bulletin.*]

THE WORLD'S LATEST LITERATURE

Journal of the American Medical Association.

February 27, 1904. [Vol. XLII, No. 9.]

1. The Classification and Diagnostic Guides of Intestinal Obstruction. H. TUHOLSKE.
2. Report on Two of the Children Operated on by Lorenz. HARRY M. SHERMAN.
3. Table Wines. Are Their Uses to be Encouraged? HENRY O. MARCY.
4. The Decapsulation of the Kidney, with Reference to the Concomitant Intraocular Complications in the Chronic Forms of Nephritis. GEORGE F. SUKER.
5. Some Remarks Concerning the Ocular and Aural Requirements of Railroad Employes. FRANK ALLPORT.
6. The Blue Light Treatment in Diseases of the Skin. LOUIS E. SCHMIDT.
7. Strangulated Femoral Hernia Containing Appendix: Report of Two Cases. J. HENRY BARBAT.

1.—Classification and Diagnostic Guides of Intestinal Obstruction.—H. Tuholske speaks first of congenital and acquired ileus and divides the latter into dynamic or paralytic and mechanical ileus. Dynamic ileus may be due to inflammation, mechanical or chemic irritation, infection causing gas accumulation, embolism of the superior mesenteric, changes in the central nervous system. Mechanical ileus is divided into cases due to strangulation and obturation. Strangulation may come from peritoneal adhesions, obturation from gallstones, intestinal concretions, foreign bodies, fecal impactions, strictures, sarcoma, intussusception. In dynamic ileus peritonitis opens the scene, in other forms it closes it. The diagnosis of obstruction is not so difficult as the finding of the underlying anatomic conditions and site. The writer discusses the differentiations in a detail which does not lend itself to abstracting. [H.M.]

2.—Two Children Operated on by Lorenz.—H. M. Sherman removed the splints in the presence of other surgeons, and radiographs were made immediately. These he presents. In the first case the head was in a subcutaneous position in the outer part of Scarpa's triangle, while the trochanter was somewhere behind and internal to it. The condition was not favorable to stable support, and a cutting operation was agreed to. The head was found thrust through the torn capsule and lying among the muscles. The trochanter had been crowded nearly into the acetabulum. The latter was shallow, but the head was put easily into it. Little capsule was left in front of the head. It is impossible to avoid the conclusion that manipulation that weakens the capsule is a detriment. No condition exposed by this incision could have been counted on to prevent backward movement. If the movement took place, the head entangled in the rent would not move so fast as the trochanter, and an outward rotation of the limb would occur. The rent in the capsule being on the distal side of the constriction, all crowding of the head through the latter and into the acetabulum is lost. If the head is now put in the acetabulum, it is wasted effort, for the proximal part of the capsule is stretched over the cavity and not only closes it, but makes it still more shallow. In the second case, still unopened, the head points forward above the acetabulum and the trochanter backward and behind the latter. [H.M.]

3.—Table Wines.—H. O. Marcy discusses the separation of water from wines by crystallizing out at low temperatures, leaving the alcoholic and essential qualities. Fruit juices can be concentrated in the same way, making many additions to our table delicacies. Beverages which many think preferable to costly wines can thus be manufactured and preserved. He reviews the objections to alcoholic drinks and believes these fruit juices will ultimately supplant them. [H.M.]

4.—See *American Medicine*, Vol. V, No. 20, p. 784.

5.—The Ocular and Aural Requirements of Railroad Employes.—F. Allport gives the total of personal accidents in one year as 51,743, and of these 7,123 were killed. A majority of these were probably preventable, due to carelessness or physical defect. Inquiries sent to 244 railroads elicited the fact that 77 require systematic eye and ear examination; 26 roads require perfection and allow no concessions to old employes; 41 require perfection from new employes and allow various concessions to old employes. No road allows new employes to wear glasses; 74 allow old employes to wear glasses for distance. The writer gives the report of the Committee of the Section on

Ophthalmology, with the remodeled resolutions passed by the House of Delegates. He does not endorse the idea of testing with both eyes open and of ignoring the condition of the worst eye. He increasingly feels that liberal concessions should be made to old employes, and the utmost paucity of vision consistent with safety be liberally computed. Experience and good judgment compensate for physical defects. Perfection should be required in the beginning, with not more than 1½ D. of apparent hypermetropia. [H.M.]

6.—Blue Light in Skin Diseases.—L. E. Schmidt contrasts the red and blue rays, the latter having a soothing effect just opposite to the action of the former. He uses an arc lamp with a reflector which concentrates light on a blue glass screen. Large surfaces may be treated, and it is not necessary to protect healthy parts. Distance from the screen varies from a few inches to a foot, time, from a few minutes to a half hour. Treatments may be given once or twice daily. The actinic action accompanying blue rays is much less than those accompanying ultraviolet rays. Freedom from heat rays is regulated by the distance of the reflector, and the patient from the screen. The blue light has been successful in a number of cases in which röntgen rays in his hands failed. Its advantages are simplicity in application, large and small surfaces may be treated, there are no untoward effects, the results are favorable, and the apparatus inexpensive. [H.M.]

7.—Strangulated Femoral Hernia Containing Appendix.—J. H. Barbat has come across 100 cases in which the appendix was found in femoral hernia, but in only a few of these was it the sole occupant, and in only one or two has a primary strangulation occurred. In order that it may pass through the hernial ring it must be free and possess a mesoappendix sufficiently long. No case has been reported in which the appendix was found in a left femoral hernia. In 1 of the 2 cases he reports the strangulation was secondary to swelling, which followed appendicitis. It would take little swelling to cut off circulation and produce necrosis. [H.M.]

2. Questions of Urinalysis Bearing upon the Diagnosis of Contracted Kidney. BEVERLEY ROBINSON.
3. The Hot Full-bath. FRIEDRICH GHOSSE.
4. The Ordinary Röntgen and Ultraviolet Rays in the Treatment of Tuberculosis. J. B. RANSOM.
5. Antistreptococcus Serum in Pernicious Anemia. JAMES J. WALSH.
6. Hematoma of the Sternocleidomastoid Muscle: A Study of three Cases. THERON WENDELL KILMER.

1.—Faciohypoglossal Nerve Anastomosis.—A. S. Taylor and L. P. Clark report having performed this anastomosis on 3 patients. In none of these had the operation been performed sufficiently long to determine what the result would be, though a favorable prognosis is given in each instance. Their conclusions are: 1. The best results follow when the cause of the paralysis has been a traumatic division of the nerve. Less hopeful of complete recovery are those cases due to neuritis, especially when caused by suppurative mastoiditis. 2. The longer the time between the paralysis and the anastomosis, the slower and less complete is apt to be the recovery. In traumatic paralysis, anastomosis should be immediate. In interstitial neuritis it is necessary to wait a few months for signs of spontaneous recovery, which so often occur. At the end of 3 months to 6 months of treatment the neurologist can decide the propriety of operating. In the suppurative forms operation should be done as soon as the danger of infection of the wound is passed, as there is small likelihood of spontaneous recovery. 3. The condition of the paralyzed muscles, flaccidity, contracture, spasm, changes in electric reaction, and, most particularly, the degree of atrophy, is important. The more atrophy the less hope. Therefore, massage and electricity must be systematically used from the onset of the paralysis. 4. The technic must be precise and delicate. The nerves must not be pinched nor unduly handled, the sutures must be fine, and involve only the nerve sheaths. The degree and duration of operative appearance of temporary interference with the functions of the hypoglossal nerve, were directly proportionate to

the traumatism inflicted during operation. There must be the least possible amount of scar tissue. 5. The first degree of recovery consists in symmetry of the face during quiescence, but without volitional muscle control. The next consists in the return of volitional muscle control, but with the paralyzed side of the face uninfluenced by the emotions. The third and complete degree consists in the return of emotional control of the face. [A.B.C.]

2.—Urinary Analysis and its Bearing upon the Diagnosis of Contracted Kidney.—Beverley Robinson states that this analysis is related to 3 classes of patients: (1) Patients whom we believe are suffering from complicated contracted kidney; (2) patients whom we suspect of having contracted kidney, in addition to neurasthenia or other disease; (3) patients, particularly women, whose urinary analysis shows no other evidence of contracted kidney than continued low specific gravity and deficient excretion of urea. In certain instances urinary analysis alone will not enable us to make an exact diagnosis, and in every case it is desirable to consider all other clinical signs and symptoms, and even then at times we shall find it difficult or impossible to pronounce ourselves in exact and positive terms about a given case. Not infrequently the primary form and the arteriosclerotic form of contracted kidney described by authors are essentially one and the same anatomically, and satisfactory explanation of different urinary signs at various stages of the disease remains to be given. [A.B.C.]

3.—The Hot Full-Bath.—F. Grosse calls attention to the indiscriminate use of the terms warm and hot and its harmfulness. Baths from 98° to 102° may be of moderately long duration before inducing heart troubles, but one of 106° or 107° should not last longer than 15 minutes, and those above not longer than 10 minutes. Those from 98° to 102° are sedative and warm, those above 106° are exciting and hot. The limit of endurance with us seems to be 109° or 110°, with a duration of 6 to 10 minutes. The patient should enter slowly, 1 or 2 minutes elapsing before full immersion. The hot bath is indicated to increase metabolism, to eliminate toxic substances, to remove exudations and stagnations in internal organs, to cure rhinitis, laryngitis, bronchitis, bronchopneumonia, pseudocroup, asthma, emphysema, dry pleurisy, kidney troubles, rheumatism—especially the chronic form, chlorosis, osteomalacia, pelvic diseases, syphilis, obstinate skin diseases, scrofulous corneal affections, iritis, neuritis, and neuralgia. It is contraindicated in maladies of the central nervous system, marasmus, uncompensated heart troubles, nervous irritation with atheroma, with presence of fetid masses in the intestines, or in cases of pus collections anywhere in the body. [H.M.]

4.—Röntgen and Ultraviolet Rays in the Treatment of Tuberculosis.—J. B. Ransom reports 40 instances in which tuberculosis in various parts of the body was treated by means of the röntgen rays, and refers to certain cases reported by Finsen as having been treated with ultraviolet light. He states that röntgen and ultraviolet rays are especially adapted to the treatment of superficial tuberculous lesions. As to deep-seated pulmonary lesions, the number of cases treated is too small and the time elapsing too short to estimate fully the results, but he is impressed with the efficiency of these therapeutic agents so far as they have been tried. The röntgen rays relieve pain, permit sleep, stimulate local circulation, and materially lessen the expectoration. In hemorrhagic cases, he had 3 slight hemorrhages immediately following exposures in cases in which hemorrhages had been of recent origin. As to how the röntgen ray produces its results in the relief of tuberculous conditions we do not know. It is believed by many to be due to the development of nascent oxygen in the tissues, or ozone, and their effect in setting up interchemic action. [A.B.C.]

6.—Hematoma of the Sternomastoid Muscles.—T. Wendell Kilmer reports 3 cases. He says: "Hematoma of the sternomastoid is invariably caused by injury to that muscle during the birth of the child. It is more frequently seen in breech than in vertex cases, although any undue traction exerted on the presenting head may also cause a hematoma. A partial asphyxia of the infant greatly increases the danger of this injury on account of the atonicity of the muscle and the

weakened bloodvessel wall. The hemorrhage takes place into the sheath of the sternocleidomastoid muscle. Hematoma of the sternomastoid is not usually noticed by the mother or nurse until long after the injury has taken place." The diagnosis is comparatively easy and the hematoma is differentiated from tuberculous node by the fact that it is in the substance of the sternomastoid muscle. The treatment is gentle massage and manipulation until the tumor subsides. Surgical interference is rarely necessary. [A.B.C.]

1.—Aerophagia.—Heinrich Stern says this condition may be of hysteric or nonhysteric origin. During the presence of gas within the stomach the patient may exhibit pronounced anxiety, shortness of respiration, impending suffocation, cardiac palpitation, cephalalgia, and vertigo. Anorexia and vomiting are of frequent occurrence; weakness, emaciation, irritability, and nervous phenomena of varying degree are the further natural results. Extensive work in the open air and overindulgence in outdoor sports are frequently responsible for the production of aerophagia. The air may be transmitted to the duodenum and other parts of the intestinal tract. The treatment should be primarily of a prophylactic nature. When the condition is of hysteric origin the best treatment is rest and sleep, which latter, if necessary, should be induced artificially. When the condition is acute, the stomach-tube should be employed to facilitate the exit of the air. This may be followed by irrigation with large quantities of water of about 43° C., to which has been added chloroform water (about 10 cc. per liter). If necessary, a teaspoonful of the following prescription may be given every 3 hours for the next day or two: Bismuthi salicylatis, 15 gm. (225 gr.); mentholi, 1 gm. (15 gr.); mucilaginis acaciae, sufficient quantity to make 90 gm. (3 oz.). In cases accompanied by severe pain, opium or its preparations have to be resorted to. Castor oil is of decided benefit in ameliorating the pronounced intestinal tympany following aerophagia. [C.A.O.]

2.—See American Medicine, Vol. VI, No. 14, p. 578.

4.—Osteomyelitis.—H. J. Williams presents the records of 17 cases of osteomyelitis and reviews the literature of the subject. Fifteen of the cases were in children under 16, 2 were in adults over 25; the youngest patient was 2 months old, and the oldest 56 years. The disease was present in the upper extremity in 5 patients; in the lower limb in 8, in the lower jaw in 4; the humerus, the femur, and the lower jaw were most frequently involved. Eight of the cases were seen early enough to do conservative operations; in the remainder, late operations were necessary. No deaths occurred. Williams says that the condition is the result of the migrations of any of the pus-producing organisms. Of the 17 cases, staphylococci were present in 5, once streptococci alone, and once streptococci and staphylococci existed together, in the same infection. This septic process is almost exclusively a disease of the period of bone development and growth, beginning, with but few exceptions, in the growing tissues in the end of the diaphysis near the epiphyseal cartilage on the side remote from the joint in childhood. The disease is generally a secondary process in a purely bacterial form of pyemia. The diseases most frequently mistaken for osteomyelitis are deep-seated cellular abscess, erysipelas, typhoid fever, and acute rheumatism. Almost every case that is recognized immediately and treated promptly by surgical methods can be saved from disfigurement and permanent disability. [C.A.O.]

5.—Artificial Fluorescence of Living Tissue.—W. J. Morton reports several cases in which this method has been successfully used. The procedure involves 2 distinct factors: 1. The safe introduction of solutions or mixtures capable of fluorescence or phosphorescence. 2. The employment of an

agency, externally or internally, capable of exciting fluorescence in the introduced solutions, mixtures and substances. The administration of the fluorescible materials, solutions and medicines may be by the mouth, by introduction in bulk within cavities, by hypodermic injections into the circulation, or locally into a tumor, by cataphoresis, or by simple topical applications of washes and ointments. The agency for excitation is preferably radium but the röntgen radiation may less preferably be used in the usual manner from the outside; or any of the various forms of arc lights used in the Finsen ray treatment, or simply (in illuminating cavities) an ordinary electric light or any source of artificial light which can conveniently give its light locally. Solutions of quinin bisulfate and of esculin may be used. Other solutions whose desirability may be considered are fluorescein, resorcin, orcin, eosin, fraxin, uranin, rhodamin and petrolatum jelly. The method is capable of general application, and is not restricted in its usefulness to any specific disease. The first diseases which suggest themselves as suited for treatment by this means are tuberculosis, carcinoma, chronic malarial affections, Hodgkin's disease, and all those affections which are associated with the presence of a specific microbe; also nervous diseases, like epilepsy and insanity, as well as diseases of the skin. [C.A.O.]

1.—**Economic Value of Medical Science.**—W. G. Thompson notes the economic benefit derived from the public having been taught not to run from epidemics, thus paralyzing all commercial interests, but to combat them intelligently. He calls attention to the great reduction in mortality from yellow fever, bubonic plague, the practical extermination in many countries of typhus and leprosy, the promising outlook as to the extermination of malaria, typhoid, and epidemic dysentery, the reduction in smallpox cases, and in some places of tuberculosis. Not least among important aspects of medical science is the large capital invested in buildings and appliances, such as schools, hospitals, and asylums. There are other millions invested exclusively in medical products. Studies in psychopathology have had many practical results in criminology, and the treatment of the insane. In the department of hygiene and sanitation, medical science has newly established a wide field of industry. Its purely commercial value makes a national medical department desirable. No municipality should be permitted to conceal for its own profit a local epidemic. No State should be allowed to pollute with typhoid a stream flowing into another State. Governments are realizing that the practical applications of medical science are as essential as proficiency in fighting to the preservation of their armies and navies. It is not generally appreciated that medical science is revolutionizing applied botany and agriculture, through the discoveries as to parasites, etc. The science of biology had its origin in that of medicine. Meteorology owes its inception to the observations of army surgeons. Medicine has opened a new occupation to women as physicians and nurses. It has developed a voluminous literature involving large financial interests. It has prolonged life. [H.M.]

2.—**Etiology of Rachitis.**—P. W. Nathan believes the defective calcification of the bones is due to a constitutional vice. The amount of calcium in ordinary foods is always ample. The insoluble calcium salts in milk curd can be redissolved only by an acid and it depends on the quantity of HCl whether a sufficient amount of calcium is made soluble. Deficiency of HCl is said to be due to deficient NaCl and this to excess of K in the food, but there is always enough NaCl to prevent NaCl starvation. Only a very small amount of calcium

is necessary for the organism and it is certain that its absence from food is not the ordinary cause of rachitis. Even in the severest forms of the disease, soluble calcium is absorbed in the same proportion as in health. Improvement is no more frequent when it is administered therapeutically than when nothing at all is given. He therefore concludes that deficiency in quantity or faulty absorption of the calcium ingested is not the cause of rachitis. [H.M.]

3.—**Splint for Fracture of the Mandible.**—C. B. Knapp states that he has devised a new splint in the treatment of fracture of the mandible, the merit of which consists in preventing the anterior fragment being pulled downward and backward by the muscles of the hyoid bone and the posterior fragment being displaced in the opposite direction by the pterygoid, masseter, and temporal muscles. To accomplish this he takes a strip of tin, turns up one end to form a gutter, carries the strip from the forehead over the vertex and well under the occipital protuberance. This is made secure by a plaster bandage. Strips of adhesive plaster from the under surface of the chin to the gutter of the splint give the desired upward and forward traction. He has treated 2 patients with this splint, the results being entirely satisfactory. [A.B.C.]

4.—**Thrush.**—H. Illoway reminds us that this disease, due to filth, may develop in an infant otherwise healthy, and that since better knowledge as to the care of infants has become more widespread, the disease has become of rather rare occurrence. The parasite is always introduced from without. The infant will not or cannot nurse, and inanition soon sets in. He reviews the usual remedies, which are not certain and rapid enough in their action in grave cases. He has found one thorough application of tincture of iodine, 2 gm. ($\frac{1}{2}$ fl. oz.) in glycerin 14 gm. ($3\frac{1}{2}$ fl. oz.) sufficient to remove the parasite even in the worst cases. [H.M.]

5.—**Internal Treatment of the Bladder.**—Louis Stern states that since the majority of vesicle, urethral, and prostatic troubles have, of late years, been recognized as of bacterial origin, internal treatment of these affections has largely given way to local treatment. He advocates internal treatment, especially for many vesicle affections, and advises the use of helmitol or hexamethylenetetramin anhydromethylene citrate. This is a derivative of hexamethylenetetramin or urotropin. The latter drug has heretofore been extensively used for vesicle inflammations, but in certain instances it produced renal irritation and albuminuria, and in strongly ammoniac urine urotropin is not decomposed, and its formaldehyd is consequently not given off to act as the antiseptic agent. Stern has used helmitol in a number of cases during the past 6 months, and thinks it superior to urotropin. He quotes from Müller, of Zurich, who states that helmitol has a much more pronounced antibacterial action than urotropin. A series of cases is reported. [A.B.C.]

6.—**Chloroform in Labor.**—E. Ricketts thinks the importance of conserving the maternal force during the puerperal state—and especially during delivery—has not been sufficiently emphasized. Chloroform during delivery is the remedy that is faithfully to conserve the energy of the patient. Lacerations and contusions resulting from childbirth are far more frequent following so-called normal labor than those carefully delivered under chloroform. The exhaustion of the pregnant uterus by unsuccessful effort at delivery in prolonged labor may be the cause of postpartum hemorrhage after final delivery under anesthesia. He quotes Simpson's rules with approval as follows: 1. Begin the inhalation of chloroform when the patient complains of much pain, generally toward the end of the first stage. 2. Always inculcate perfect quietness around the patient, particularly when commencing to give the chloroform. 3. Only give it during the pains, and withdraw it during the intervals. 4. When given during this stage the anesthesia need not be deep, unless the suffering be great or the system of anesthesia disagreeable. 5. As the second stage progresses make the anesthesia so complete as to destroy all sensibility. 6. Do not allow the urinary bladder to become overdistended. 7. Do not restrain the patient to one position. 8. Be sure to remove the chloroform as soon as the child is born. 9. Do not awake the patient artificially. [W.K.]

CLINICAL MEDICINE

DAVID RIESMAN

A. O. J. KELLY

EDITORIAL COMMENT

The etiology of leprosy is still a chaotic question. Its origin from the eating of fish is a thesis still vigorously defended by its original apostle, Mr. Jonathan Hutchinson, of London. Strong opposition does not appear to have disposed him to abate one jot or one tittle of his claim to the discovery and promulgation of an illuminating source of scientific light. Still the unprejudiced (and discriminating) observer who has been assured on good authority that Cashmere, in Asia, and Kaffirland, in Africa, whose inhabitants habitually *eat no fish*, display an unusually large proportion of lepers, will find some difficulty in accepting the absolute dictum of the eminent English surgeon. The difficulty will not be diminished by recollecting the undoubted fact that the poor inhabitants of the coasts of Ireland subsist very largely upon fish—in all the most objectionable forms of preservation and cookery, and yet a case of leprosy is never heard of among them. Mr. Hutchinson has endeavored to prove that a certain proportion of fish eating actually does go on in the Asiatic and African regions referred to, and that the existing plague, so far as it goes, may thus be satisfactorily accounted for. But the immunity of the Emerald Isle calls for a special item of explanation. Did St. Patrick banish the *Bacillus lepræ* on the memorable occasion on which he expelled all poisonous reptiles from the borders of the “*Insula Sanctorum et Doctorum*?”

Leprosy and Emigration.—M. Jeanselme has recently given an interesting account—historic, geographic, and ethnologic—of the relationship between the currents of emigration and the dissemination of leprosy in modern times. At the dawn of the modern era, the principal endemic foci of leprosy were found in Africa (west coast), India, and China (southern). One of the many malignant influences on the New World with which the Spaniards have been credited is the introduction of leprosy. The grounds for this accusation have, it is almost unnecessary to say, been disputed. But it is a historic fact that Cortez found it necessary to open a leper's house in Mexico as soon as he had established himself there. And in the parts of this continent where the aboriginal race “*a été refoulée, mais non pas détruite, aux Guyanes par exemple*,” it is still noticeable that the inhabitants possess their old immunity from the loathsome disease. The Chinese fought and emigrated southward, and carried the infection into Annam, Burmah, Cochin-China, etc. The city of Singapore is still a veritable Chinese colony. And in that part of the great eastern continent there is a deplorable prevalence of leprosy. The Chinese have disseminated leprosy in all directions of their emigration. The torrent of Celestials which was attracted by the discovery of Australian gold in 1851 accounts for the infection of the junior continent. It is worthy of note, too, that the importation of negro slaves to America in the preemancipation times was largely instrumental in the dissemination of leprosy in our own part of this continent.

REVIEW OF LITERATURE

The Origin of Pulmonary Tuberculosis and the Combat against Tuberculosis.—Behring¹ says that everyone is somewhat tuberculous and that this disease is produced only by the tubercle bacilli. This bacillus may vary slightly as to form and shape, and considerably as to virulence, but with it all there is but one variety of tubercle bacilli even though Koch maintains the type variety of the bovine and human bacillus. Naegali examined the cadavers in the postmortem room at Zurich and found practically all above 30 to be tuberculous; 96% of the individuals between 18 and 30, 50% of those between

14 and 18, 33% of those between 5 and 14, 17% of those between 1 and 5, contained tuberculous foci. Infants less than 12 months old were usually found uninfected. It is difficult to diagnose the condition in the living being unless by means of the tuberculin test. This reaction is induced by coagulation and agglutination, when tuberculin comes in contact with the otherwise soluble antibody produced in the tissues of the body by the action of the tubercle bacilli. Franz, of Budapest, employing this test in doses of from 1 mg. to 5 mg., found that of soldiers in their first year of service 61%, in their second year 68%, reacted positively; using 10 mg., 96% reacted. Berend employed the same dose in 96 infants with absolutely negative results. By means of Jousset's inocscopy, tubercle bacilli were discovered in many cases of doubtful exudative disease. These figures prove the uselessness of quarantining against tuberculosis in densely populated places, the difference between tuberculous infection and “consumption,” and the spontaneous curability of the disease in many people. He says the light infections are usually cured while the grave infections lead to a fatal termination. Our aim should be to prevent the latter cases in particular, and to do this we must be well-informed about their etiology. Behring does not believe in the importance of infection by traumatism, direct contact, inhalation, or heredity; the latter does not exist as more than a disposition, although a few authentic cases of placental infection exist. Most all cases arise after birth and, according to Behring, the milk fed to infants is the chief source of tuberculosis, thus emphasizing the infection of milk before ingestion. A postnatal heredity may be spoken of, as the milk fed to children in tuberculous families is more likely to be infected than in nontuberculous. The reason why infants using infected milk are more likely to contract the disease is, that their digestive apparatus, just as among lower animals, is devoid of a continuous epithelial lining, the gaps allowing the passage of albumin and bacteria like any porous filter. He quotes and discusses his numerous experiments which have established those facts. The first signs of the infection are usually seen about the glands of the neck, the lungs being affected secondarily. Another proof of the danger of the milk is seen in the comparative mortality statistics of bottle-fed and breast-fed infants. A point of importance, therefore, in the combat against tuberculosis is a method of preservation of milk; it should be pasteurized at its place of production and not only after it reaches its point of distribution. Infants and coughing consumptives should be kept at respectful distance from each other, but the same rules hold good in the cases of older people, whose digestive apparatus may be suspected of having epithelial defects as in gastric diseases, after fevers, etc. Tuberculous infection may remain latent for years or even for life, but under predisposing conditions it may develop into pulmonary tuberculosis, which is thus traced to infection in infancy. Once the disease is developed, such patients should be given the benefits of climatic and dietetic treatment; they should be taught so as to prevent their state from becoming worse and worse. The ideal treatment, however, is not the cure of tuberculosis, but the prevention of it, and Behring does this successfully now in bovines by means of his tuberculosis vaccine. He reviews fully the brilliant results which he has achieved in the immunization of cattle throughout Germany. He has been doing this by means of injections thus far, but hopes to achieve the same results by feeding calves his virus by mouth; if so, he thinks the method could also be utilized for infants. Much more promising is the antitoxin method; the milk of highly immunized cows must certainly contain protective substances, which can be conveyed successfully to man, the only thing necessary is to discover something which will conserve these immune bodies. The immunity produced by these antibodies, which would naturally be of short duration, could be prolonged by combining the living virus with the antibodies. He ends his article by disproving Koch's contention concerning the difference between human and bovine tubercle bacilli. Koch bases his argument on 3 points: Human bacilli will not produce “*perlsucht*” in cattle. This fact proves, according to Behring, that they are the same. Human bacilli will immunize cattle against the disease, just as vaccine immunizes against smallpox; no one says vaccine bacilli and smallpox bacilli differ. The absence of danger

¹ Deutsche medicinische Wochenschrift, 1903, xxix, No. 39.

of bovine tuberculosis (Koch's second argument) is a statistical and not experimental deduction, and has been disproved repeatedly. The logical deduction of his first 2 arguments (the superfluity of sanitary laws and regulations against food products from infected bovines) is considered absolutely wrong by Behring, so far at least as infants are concerned, when the anatomic structure of their gastrointestinal tract is taken into consideration. [E.L.]

Bloody Vomit in Peritonitis.—W. P. Gerassimoritch¹ reports a series of cases with bloody vomiting in the course of peritonitis. The patients were all children, early life being an acknowledged predisposing factor. One of the first to observe bloody vomiting in appendicitis was Dieulafoy, who explained the phenomenon by toxic action. Our author does not agree with the assertion that bloody vomit is due to appendicitis. He ascribes it to peritonitis of a purulent nature. The exit of blood is due primarily to diapedesis. Though small erosions are often found, they are a secondary factor. The minute hemorrhages per diapedesis are brought about by toxic vessel-changes, by vasomotor paralysis, by local stasis, and by heightened blood-pressure acting in unison. Bloody vomiting has an ominous prognostic meaning. [L.J.]

Sudden Heart Failure in Toxemic Conditions.—Arthur Stanley² discusses this subject particularly with reference to the toxemia of infectious diseases with especial reference to diphtheria and beriberi. His conclusions are: 1. That beriberi and diphtheria have a marked degenerative action on the heart muscle, which frequently causes fatal circulatory failure. 2. In this respect beriberi and diphtheria resemble other toxemias, such as influenza, alcohol and arsenic poisoning, which often cause peripheral neuritis and also toxemic diseases, such as typhoid, plague, and acute rheumatism. 3. Beriberi and diphtheria are the diseases par excellence in which sudden heart failure occurs. 4. The heart muscle degeneration is not a second result of neuritis of the vagus. 5. The heart muscle degeneration takes place as a rule before skeletal muscle degeneration, and is the result probably of direct action of the toxin and not a secondary result of nerve change. 6. Sudden heart failure does not indicate a sudden lesion, but rather is the result of a gradual increasing heart weakness from cardiac muscle degeneration which may be precipitated by any sudden exhaustion, and more frequently is the result of the principle of "all or nothing," the transition of "all to nothing" being necessarily rapid. 7. The cardiac physical signs in beriberi closely resemble those found in diphtheria, and are of prominent importance in prognosis and treatment. [A.B.C.]

Immunization of Cattle against Tuberculosis.—F. Neufeld³ reports concerning the successful immunization tests against tuberculosis made in Koch's laboratory. Goats, asses, and bovines were made immune to the disease. The degree of immunity and the agglutinating power which the blood-serum of these animals possessed seemed in direct relation as pointed out by Koch; the greater the agglutinating power, the higher their immunity. Immunization was brought about by first injecting cultures of dead bacteria; this was followed by gradually increased doses of living organism, first of the human types, and later of the bovine variety; it was his aim to reach as large a dose as possible. Some variations from this general plan were tried several times and with success. The immunized animals could stand doses of bovine tuberculosis agent, which proved fatal invariably to control animals. When dead cultures alone preceded bovine bacilli, immunization was not attained. In some cases, where living organisms were injected after dead cultures, acute poisoning developed, leading to a speedy death. This was in no case due to tuberculosis, but to intoxication. The dose producing this intoxication varied in different animals; a smaller dose of bovine tubercle bacilli produced it than of human organisms. Dead cultures alone, even in large doses, never produced this intoxication. This is the more remarkable, as dead tubercle bacilli have the same power as living cultures to induce local toxic action; that is, the formation of nodules. In some of the animals chronic intoxication

developed after very large doses. Thus immunization was sometimes difficult to produce. Intravenous injections were found to be more powerful and certain in action than subcutaneous. [E.L.]

New Signs of Tetany.—R. A. Peters¹ says a curious new sign of the affection is elicited by passing a current in such manner that the anode is on the sternum while the cathode is over the lower cervical vertebrae. When the circuit is closed, convulsive jerks are seen in the arms and hands, very similar to the movements of a toy clown when the string is pulled. This sign, according to the author, indicates a pathologic state of affairs in the roots of the spinal nerves. Another noteworthy feature of tetany is the increased production of cerebrospinal fluid, as demonstrated by the author. This excess bears a direct ratio to the duration and severity of the disease and is also presumably indicative of spinal involvement. It is the author's conviction that tetany is essentially a disease of the spinal cord and its adjacent structures (meninges, muscles, bones). He cannot agree with the view that eclampsia infantum and so-called latent tetany are related conditions. [L.J.]

GENERAL SURGERY

MARTIN B. TINKER

A. B. CRAIG

C. A. ORR

REVIEW OF LITERATURE

Surgical Treatment of Perforation in Typhoid Fever.

—M. Cazin² makes a strong plea for surgical intervention in every case of typhoid perforation, believing that this offers in almost all cases the only chance of recovery. He reviews the successive steps in the development of this phase of surgical practice. Carefully compiled statistics show a recovery in 27.63% of cases treated by operation, the mortality including many cases where the operation was delayed until the patient was in *extremis*. Hesitation on the part of the surgeon is frequently due to difficulties of diagnosis. Perforation is characterized by a more or less acute pain, coming on suddenly, and being well localized in the lower median or right section of the abdomen. Muscular resistance frequently develops, and is a valuable sign. Leukocytosis is of little value diagnostically. Operation should be performed as soon as possible after making the diagnosis. It is not advisable to wait for recovery from the shock of the perforation, as the danger of generalized peritonitis is too great. Operation should be performed in all cases even when it seems too late to be of benefit. General anesthesia is to be preferred over local. Some surgeons employ the median, and others the lateral incision. In the intestine the Lembert suture is to be preferred, using silk, and placing the suture some distance from the friable edge of the perforation. The abdominal cavity should always be thoroughly flushed, and efficient drainage provided for. [B.K.]

Intestinal Perforation in Typhoid Fever.—Richard Hart and Astley P. C. Ashhurst³ have compiled all the previously reported cases, which now number 362. Early in the operative treatment of this affection the mortality was 90%, while in the period from 1894 to 1898, inclusive, it was reduced to 70%, which the authors believe is about the present death-rate. The male sex is more liable than the female in the proportion of 4 to 1. Of 279 cases in which the age is known, over 12% occurred in patients under 15, and over 54% between 15 and 30; 33% over 30. Of 286 cases in which is known the stage of disease when perforation occurred, 6 happened in the first week; 162, or 56%, in the second and third weeks, and 42% in the third week. The site is mentioned in 190 cases, and in 140, or 73%, the lesion was found within 12 inches of the cecum, and in only 4, or 2%, was it more than 3 feet from the ileocecal valve. Meckel's diverticulum was perforated 3 times, and the appendix 8 times. In only 5 instances did the patient die before the conclusion of the operation. Of the whole number, 26% finally left the surgeon's hands well. In the average case anesthetization by ether is considered best; drainage was

¹ Russki Vrach, November 1, 1903.

² La Semaine Médicale, January 6, 1904.

³ Annals of Surgery, January, 1904.

necessary in nearly every case. The authors now prefer gauze to tube drainage. Of 26 exploratory laparotomies wherein no perforation was found, 10 died, a mortality of 38.5%; only 3 of these, however, died in less than 12 hours after the operation. [A.B.C.]

Partial Enterocoele.—Lucius W. Hotchkiss¹ defines this condition as one in which a portion of the gut wall is pushed into the hernial sac, the latter in these cases is generally small; it contains a portion of intestinal wall, and in some instances omentum. In some cases a preexisting hernia has been present. Usually after some strain a small swelling develops at the site of one of the hernial openings, becomes painful, and is found to be a pressure enterocoele. Adhesions between the gut and neck of the sac protect the general peritoneum from infection for a time, but finally this barrier is overcome and a general peritonitis develops; the condition is analogous to strangulated hernia, and resection of the gut, in most instances, must be resorted to. He reports 6 cases, under the following captions: (1) Strangulated inguinal hernia (partial enterocoele), general peritonitis, death; (2) strangulated inguinal hernia (right partial enterocoele), gangrene of gut, resection, Murphy button, pneumonia, thrombosis of left saphenous vein, recovery; (3) strangulated partial enterocoele, operation, reduction, general peritonitis, secondary operation, death; (4) strangulated partial enterocoele, gangrene of gut, perforation, resection, end-to-end anastomosis by Maunsell's method, death; (5) strangulated right partial enterocoele, resection, Murphy button, recovery; (6) strangulated Littre hernia, gangrene, resection of gut, anastomosis by the Murphy button, recovery. [A.B.C.]

Suprapubic Prostatectomy.—Sir Thornley Stoker² reports 3 cases and comments at length upon the operation, stating that mere removal of the gland is usually a more simple matter than the after-treatment of the cases. He holds that if the prostate is essentially enlarged, or if a nodular condition of the gland due to separate capsulated tumors of an adenomatous or myomatous nature exists, the entire gland should be removed. He does not believe that the so-called middle lobe exists, but rather that the outgrowth of a separate adenoma or myoma is what is usually so christened. He employs the suprapubic route, insisting that the operator should snip with scissors well into the substance of the prostate before enucleation is attempted. In this way he is sure to get within the capsule of the pelvic fascia and beyond the vascular region. Records seem to show that cases do just as well in which the prostatic urethra has been removed as in those in which it is preserved. The chief source of hemorrhage is from the veins between the bladder and the fascial capsule or between the latter and the true capsule. When enucleation is attempted hemorrhage is controlled with hot irrigation of boric solution. He no longer uses a Peterson's bag in the rectum, holding that it is useless. There are 3 conditions of senile enlargement of the prostate: (1) A true hypertrophy of the gland without any interstitial growths; (2) the existence upon and within the substance of the prostate of one or more encapsulated tumors distinct from the substance of the gland proper and either myomatous or adenomatous in structure; (3) a mixed condition of true hypertrophy and interstitial growths of the second class. This condition is much the most common, the tumors may eventually reduce the prostate to a state of pressure atrophy or cause it to become a mere capsule for adventitious growths. It is the latter condition which has, in all probability, given rise to so much dispute and uncertainty as to the true pathology of the enlarged prostate. [A.B.C.]

Direct Dilation of Cicatricial Esophageal Stricture.—Joseph R. Eastman¹ pays particular reference to that form of stricture caused by the swallowing of escharotics. Occasionally such strictures obstruct the lumen with a large irregular mass, causing great dilation or sacculation before the stenosis, or the lumen may be displaced from the center of the organ and the passage of the bougie thereby rendered difficult. Under such circumstances a malleable or dirigible bougie offers a distinct advantage. He employs such an instrument, which consists of a spiral wound steel wire, filed flat and smooth, and containing

a withdrawable soft lead core; the latter is so soft as to eliminate the danger of trauma or perforation. He first introduces a filiform 15 inches long, and if this meets with obstruction additional ones are introduced until one finally passes in the lumen and through the stricture, just as in the urethra. The other filiforms are now withdrawn and the spiral-wound flexible metallic bougie attached by screwing, and thus it is guided into the esophageal lumen, the filiform curling up in the stomach. The swallowing of a weak solution of cocaine or adrenalin facilitates the introduction of the instrument. [A.B.C.]

The Treatment of Prostatic Enlargement by Freyer's Method.—Gilbert Barthling¹ reports 10 cases and comments at length upon the advantages of the suprapubic route. He holds that the prostate has its own proper capsule just as has the kidney or testicle; it is surrounded by a plexus of veins and these veins, together with the prostate, are enclosed in a sheath derived from the deep perineal fascia. The increase in bulk in the prostate is due to an overgrowth of any or of all the elements of which it is composed. He employs the Tredelenburg position in operating and uses the speculum after the suprapubic incision is made to determine the exact shape and size of the enlargement within the bladder and a metal bougie is passed which helps to guide the operator in enucleating the gland. With blunt scissors he divides the mucous membrane from the prostatic enlargement and enucleates one or both of the lobes with the finger. Of the 10 patients operated upon, 3 died, though in one instance death was due to malignant disease of the colon and therefore not ascribable to the operation; one died of uremia in the third week after operation and another died of angina pectoris in the sixth week. The cases are reported in detail and his conclusions are as follows: 1. It is possible to enucleate the prostate. 2. The prostatic urethra is then almost invariably, if not always, removed with the organ. 3. If the prostatic urethra were left it would necrose from want of blood-supply. 4. Stricture does not follow the damage to the urethra. 5. The operation gives excellent results, often restoring the function of the bladder to an absolutely normal condition. [A.B.C.]

Mixed Tumors of the Salivary Glands.—Francis C. Wood² completes a continued article. His conclusions are in part as follows: 1. There is a group of extremely complicated tumors occurring in the facial region containing elements from both epiblast and mesoblast. 2. The complicated structure of the stroma, containing as it does embryonic tissue, cartilage, bone, fat, lymphoid tissue and rarely muscle fibers, is explained most easily by the assumption of an embryonic misplacement of mesoblast. 3. Twenty-four percent of the tumors examined showed undoubted presence of epithelioma—the form and relationship of the cells of the parenchyma did not furnish sufficient data to justify these cells being regarded as of endothelial origin. 4. The theory of early embryonic displacement of epiblastic tissue during the formation of the parenchyma and submaxillary glands and the branchial clefts may account for the peculiarities of the cells found. 5. The mixed tumors of the salivary glands run a clinical course strikingly different from sarcoma and carcinoma in that they grow slowly and are generally benign. The region of lymph-nodes is not invaded and recurrences are likely to remain local in a considerable portion of the cases. [A.B.C.]

The After-history of Gastric Ulcer Cases.—J. W. Russell³ succeeded in tracing the after-history of 47 of these cases. The length of time over which the histories extend varies within wide limits, starting from the first hematemeses. The length of the cases is as follows: From 2 to 3 years, 12 cases; 3 to 4 years, 5 cases; 4 to 5 years, 9 cases; 5 to 6 years, 7 cases; 6 to 7 years, 3 cases; 7 to 8 years, 2 cases; 8 to 9 years, 1 case; 9 to 10 years, 3 cases; 10 to 11 years, 2 cases; and 12 to 13 years, 3 cases. The direct mortality from the disorder amounted to 2.1%, and 42.6% of cases ended in recovery so far as present history shows; 27.7% having but a single attack, whereas 14.9% recovered after one or more relapses; 44.7% were suffering from stomach symptoms of more or less severity at the time of their last report,

¹ British Medical Journal, January 30, 1904.

² Annals of Surgery, February, 1904.

³ Lancet, January 30, 1904.

¹ Annals of Surgery, February, 1904.

² British Medical Journal, January 30, 1904.

and 15% were getting repeated attacks with intervals of immunity, and 30% were suffering from almost continuous pain. On the whole, he is inclined to believe that the subsequent histories of these cases afford some justification for the plea for more frequent resort to operative interference in persistent cases of gastric ulcer. At the present time, however, more evidence is needed to justify this conclusion. [A.B.C.]

TREATMENT

SOLOMON SOLIS COHEN

L. F. APPLEMAN

E. LINDAUER

EDITORIAL COMMENT

Intratracheal Injections in Asthma.—That the symptom-complex known as "asthma" is not a nosologic entity, but may result from a number of differing pathologic conditions of different etiologic origin must be conceded. Hence, no one line of treatment is applicable in all cases. In that great group of cases in which the asthmatic paroxysm is merely one of the varying manifestations of vasomotor ataxia—an urticaria or angioneurotic edema of the bronchi—no palliative remedy can compare in efficacy with the preparations of the suprarenal gland. Any route of administration, except by the stomach, is admissible. The glycerin extract, the desiccated gland substance, the watery solution of the latter, adrenalin chlorid or suprarenalin in solid form or in solution are all useful—provided the drug be so given as to be absorbed from a mucous membrane, or the solution of active principle be injected under the skin. Hypodermic injections in animals have produced local necrosis, but in the human being no untoward result has been recorded thus far and a dose of 5 minims to 20 minims of the 1 to 1,000 solution of adrenalin chlorid or of suprarenalin seems to be safe and efficacious. Bullock and Kaplan especially have reported good results with this method. We have seen no report of intratracheal injection, but it should prove useful when less energetic measures fail. Caution will be necessary, for even free spraying of the throat and nose is not devoid of danger. The writer of this has placed on record a case of edema of the pharynx and uvula from excessive use of adrenal spray by an asthmatic patient. Slight spraying or local application by cotton to the nasal mucosa of a 1 to 1,000 solution of suprarenalin, followed by the use of tablet triturates of $\frac{1}{10}$ grain to $\frac{1}{20}$ grain of suprarenalin powder upon the tongue, repeating the dose every 15 minutes, half hour, or hour, as may be needed, is the method most generally applicable and one that is highly satisfactory in averting and controlling paroxysms. For the relief of the underlying condition, much more thorough-going treatment based upon a careful study of the metabolism and other etiologic factors, is necessary. But to this we shall not now allude further.

The cases reported by Mr. Colin Campbell, of Southport, in the Liverpool *Medico-Chirurgical Journal* for January, 1904, do not belong in this group. They are striking evidences, however, of the efficacy of the special method of treatment advocated by Mr. Campbell and, hence, are worthy of serious attention; for in no affection is it so necessary to have many strings to one's bow of treatment, as in the asthmatic syndrome. The treatment referred to is the intratracheal injection of menthol, glycerin, and gelatin; with the addition of other drugs—as, for example, the natural salicylates—in the presence of special indications. Large doses are used, at times as much as 30 grains of menthol with 2 fluid ounces of glycerin at a single sitting; 4 drams of a mixture of this strength is an ordinary dose. It is given during the paroxysm, if necessary, and is said to relieve the distress quickly. Preferably a chosen period of freedom is taken for the injection and the treatment is repeated daily, or twice daily, as may be necessary, until recovery is assured.

Since 1894, Mr. Campbell has treated twenty-two cases in this way and has had twenty-two recoveries; many of them, seemingly, instances of permanent cure. He believes that the direct application of menthol to the parts relieves bronchial spasm, while the glycerin compels the mucous membrane to secrete. With secretion comes expectoration and this terminates the attack. When asthma is superadded to chronic bronchial catarrh with dried-up inspissated mucus, the addition to the injection mixture of gelatin, which dissolves sputum, brings about a "complete and copious emptying of the tubes, with immediate relief of symptoms." The permanent result Mr. Campbell attributes, especially in cases of hay-asthma, to the destruction or expulsion of some germ that is acting as an exciting cause of the paroxysm.

We have had no experience with this method, but its reported success makes it worthy of a prominent place in this column. We shall be glad to learn from any of our readers who may see fit to try it in cases of asthma due to bronchial spasm or to chronic bronchial catarrh, whether or not, in expert hands—which alone should attempt intratracheal medication—its results are as good in America as in Great Britain.

REVIEW OF LITERATURE

Ocular Gymnastics in Insufficiency of Convergence and Exophoria.—W. L. Pyle points out¹ that one of the greatest causes of muscular asthenopia is insufficiency of the convergence, with or without accompanying exophoria. The prescription of proper glasses, temporary abstinence from near work, and general hygienic and tonic treatment will suffice in most cases to bring relief from the asthenopic symptoms. When, however, these measures do not afford relief, ocular gymnastics are indicated. For minor cases the "thumb or finger exercise" is of value. This consists in exercising the convergence by drawing the thumb or index-finger gradually toward the bridge of the nose, meanwhile trying to maintain a single image of the finger. The finger should be withdrawn immediately before diplopia results. This should be repeated a dozen times at each exercise, and the method should be used several times daily. The more important method is that by graduated rhythmic exercise in overcoming successively stronger prisms, bases out. Formerly prisms of 1° to 8° strength were employed. The following is the later method suggested by G. M. Gould for developing high adducting power by exercise with strong prisms: The amount of exophoria is noted, the abduction and adduction are then measured, followed by the measurement of the convergence-stimulus adduction. This is obtained by coaxing the patient to overcome as strong a pair of prisms as possible, with bases out. It will generally be found that a pair of 8° or 10° prisms is as much as can be overcome at first; but if the exophoria is not too great, it is seldom that, after a few trials, a patient cannot fuse the image of a candle flame at 20 feet (6 meters) with this handicap. The examiner should then prescribe a pair of prisms, bases out, suiting the strength to the indications, giving slightly less than the full amount of adduction power. It is of great importance to have the prism set in a well-adjusted interchangeable prism-frame. The patient is instructed to place himself 20 feet (6 meters) from a flame, and endeavor to fuse the double image; if, as is usual it is impossible for him to fuse at this distance, he must approach the flame until he gets the single image, then walk backward, keeping his gaze steadily fixed on the flame, until he reaches his starting-point. This is much more difficult for the patient than having some one withdraw the marked card from the near point to the flame; so that, whenever feasible, it is preferable to call in the assistance of a second person, particularly in the earlier days of the exercise. If the image is still single, the patient is told to hold it steadily so for about a quarter of a minute, then to raise the glasses and gaze at the flame with naked eyes for the same length of time, and repeat this 10 or 20 times 3 times a day. At the next visit the strength of the

¹ System of Physiologic Therapeutics, Vol. vii.

prisms is increased and the exercise continued at home, and at each succeeding visit an addition of about 5° may be prescribed until the patient can, without the slightest trouble, overcome a pair of 25° or 30° prisms. Patients may be educated to overcome a combined prism-strength of over 100°, base out. An arrangement may be effected with an optician to hire prisms and make the necessary changes for a very moderate charge, and the patient is saved the expense of buying a whole outfit of lenses that would be useless to him after a few weeks. Exercise should be continued for some time after apparent cure, to prevent relapse.

Opium in the Carditis of Children.—A. Morison¹ calls attention to the fact that effects are secondary causes, and when the primary cause cannot be reached it is rational to treat the former. The effects in carditis are seen in all the structures of the heart, and two facts are apparent, the uselessness of irritation or counterirritation, and the desirability of allaying local and general irritation. Stimulation of the rich nervous supply of the heart by interstitial myocarditis accounts for the cardiac unrest. It is questionable whether salicylates antidote rheumatic poison, but no other agent relieves the pain and indirectly calms the patient so quickly, and with his general relief, the irritability of the heart also. Ice also affects the heart through the nervous system, whether directly sedative or astringent to inflamed vessels. Leeching acts by relieving irritation of the nervous structures, for the amount of blood withdrawn can have little effect on the general circulation. However, the emotional excitement induced in many children by these measures renders their employment undesirable. Digitalis and strychnin, when uncombined with sedatives, have been found positively harmful. Among calnative agencies there is none more powerful than opium, when used with due care in view of the special susceptibility of children. The symptoms of this disease resemble in a measure the phenomena caused by agents antagonistic to opium, as belladonna. It is under these circumstances that opium is most beneficial. Morison has found that small hypodermics of morphin are well borne if antagonistic conditions are well marked. [H.M.]

The Cause of Death in Spartein Poisoning.—K. Muto and T. Ishizaka² have found that small doses of spartein, 0.04 gm. to 0.06 gm. ($\frac{1}{4}$ gr. to $\frac{1}{2}$ gr.), paralyze the terminal ends of the phrenic nerve and cause death by interfering with the action of the diaphragm. If artificial respiration is kept up, until the phrenic nerve power returns, the animal recovers. Large doses, more than 0.06 gm. ($\frac{1}{2}$ gr.), interfere first with the phrenic nerve, and paralyze secondarily the activity of the accessory respiratory muscles through depression of the respiratory center. The other motor nerves are not affected. [E.L.]

FORMULAS, ORIGINAL AND SELECTED.

Treatment of Amenorrhea.—M. Lutaud³ recommends the following in the treatment of amenorrhea:

Powdered damiana	0.26 gm. (4 gr.)
Powdered savine	0.10 gm. ($\frac{1}{2}$ gr.)
Powdered rue	0.10 gm. ($\frac{1}{2}$ gr.)
Powdered ginger	0.05 gm. ($\frac{1}{4}$ gr.)
Powdered saffron	0.10 gm. ($\frac{1}{2}$ gr.)

For 1 cachet. To be taken morning and evening to combat uterine congestion and to induce menstruation. [L.F.A.]

ORTHOPEDIC SURGERY

H. AUGUSTUS WILSON

EDITORIAL COMMENT

Flatfootedness appears to be increasing in civilization, or else it is observed with greater watchfulness in the physical examinations that are the order of the present day in schools as well as military life. The increasing disability that accompanies flat-feet has necessitated careful inspection of apparently normal feet in persons that were about to enter occupations requiring more than usual amount of walking and standing. It is a

matter of observation that motormen in trolley car service who stand for many continuous hours every day suffer almost unbearable pains in their feet, while the conductor, who is on his feet just as much and as continuously, is generally free from painful feet. The conductor does not stand, he walks almost constantly. Feet that are often classed as flat-feet are in reality not flat at all, but are pronated. The weakness of the muscles causes the foot to turn out, thus throwing the weight of the body upon the inner side of the foot. Lovett's¹ examination of 500 women about to become trained nurses found the great majority had acquired faulty positions of the feet, and the writer's experience has confirmed this observation. The tendency was, therefore, toward painful feet, often necessitating the discontinuance of the occupation of the nurses' training school. Dr. Sargent is quoted as saying that Sandow became flat-footed from lifting heavy weights, but this can have but little bearing upon the ordinary type of flat-foot. Sandow is an extraordinary person of phenomenal strength, by the use of which he has taxed the endurance of the human frame. The highest types of highly useful, perfectly formed feet can only be found among people who have not only not worn modern stiff, binding shoes, but whose occupations have been such as to develop the full muscle function of the feet. The best formed feet that the writer has ever seen were the Japanese and the American Indian. The civilization requires shoes with stiff unyielding soles, high heels, and ankle binders, all of which prevent the natural, normal action of feet, and thereby tend to the production of distortion and abnormalities. It is incongruous in view of these facts to still further diminish the free action of the feet by ankle corsets, or binders, or the use of the various forms of arch supporters. Physical culture can do much to enable the body to continue the use of fashion's crippling devices, the abandonment of which is required for normal use. Physical culture, while well adapted to the sound body, will cause serious injury in cases of soft rachitic bones, therefore judgment must be used in applying remedies appropriate to the peculiar conditions presented by each patient. The temporary use of mechanical arch supporters and other corrections and restraining appliances may be and are applicable to a very small proportion of weak feet, or in rachitic conditions. By the long-continued use of these appliances they cease to be beneficial, and become injurious. The proper time to discontinue the use of forms of fixation, or restraint, the manner in which it is gradually accomplished, and the methods of restoring or establishing full muscle function must receive careful attention from the physician, and not the mechanician.

REVIEW OF LITERATURE

Orthopedic Surgery, by Royal Whitman, 1903, has reached a second edition in 2 years, and has had 200 pages added. This gives evidence that this very latest textbook is kept fully abreast of the literature and practice of the present time. This is conspicuous in the chapter on congenital dislocation of the hip, the rewriting of which has necessitated entirely new cuts. The knowledge obtained from personally witnessing Lorenz reduce these dislocations is clearly portrayed; a chapter of 50 pages is devoted to this single topic, and is thoroughly up to date. The irregularities of omission and commission that occurred in the first edition have all been eliminated, and the second edition stands now a conscientious and reliable exposition of modern orthopedic surgery. Evidence of this is afforded by the fact that it is a recognized textbook in the majority of the American medical colleges. The subjects embraced within its pages are all well within the scope of orthopedic surgery. Congenital malformations and conditions which are apt to induce acquired deformities are carefully set forth. The most approved modern methods of treating existing deformities as

¹ Edinburgh Medical Journal, August, 1903.

¹ American Medicine, Vol. vi, No. 1, p. 15.

well as the prevention of their occurrence is based upon sound pathologic and physiologic basis. Withal, the reviewer finds naught to criticise and everything to commend, an unusually agreeable task.

The American Journal of Orthopedic Surgery made its first appearance in August, 1903, under the Editorial Committee composed of Drs. R. W. Lovett, of Boston, B. E. MacKensie, of Toronto, and Harry M. Sherman, of San Francisco. This will hereafter be the official publication of the American Orthopedic Association, taking the place of the former annual volume of "Transactions." The first 82 pages are devoted to the papers and discussions before the last meeting of the Association, while 26 pages are given to abstracts of orthopedic literature in foreign and domestic medical journals. The opening paper is the president's address, "The Family Physician, the Specialist, and the Patient." A single paragraph indicates the purport of Dr. L. A. Weigel's admirable address, "A judicious cooperation would inure many times to the benefit of all parties concerned." Written by a specialist the following carries conviction: "It seems to me that the doctor's position is this: that the specialist is the person who is supposed to develop an unusual amount of knowledge on a limited theme. If he is called in simply to give treatment or to aid in diagnosis on that little point, perhaps that will do; but it may do harm if he sees that one portion and overlooks the rest. He does not see justly. So I am convinced of the fact that, although young men who have settled in cities may be expected to have an unusual amount of knowledge and to be called experts, yet I am sure that in small communities the general practitioner is and always will remain the doctor."

The Correction of Deformity at the Hip, the Result of Disease: A Study of the Best Methods and Best Positions.

—Virgil P. Gibney¹ advocates subcutaneous osteotomy about the level of the lesser trochanter as the safest procedure for the correction of deformity of the hip. As to the best position of the leg after correction the concluding words of the writer are emphatic. "There are, undoubtedly, many patients who prefer a slight flexion, so that they may sit more comfortably, but these belong to the younger class. It is the opinion, therefore, of the writer of this paper that ability to sit comfortably should be sacrificed to the ability to stand and walk erect."

Subtrochanteric Osteotomy in Adults, in Adolescents, and in Young Children.—E. H. Bradford¹ says that this procedure is not to be undertaken hastily, for the dangers of non-union or delayed union would make the condition deplorable. The danger of nonunion is apparently not imminent in adults. The convalescence is slow in middle life. The danger of relapse is greater when the operation is done in childhood or in rapidly growing years. Therefore, it would seem to be better surgery to defer the operation, when possible, in young children until the period of rapid growth has been passed.

The Mechanical vs. the Operative Treatment of Rachitic Deformities, Presenting a New Osteoclast.—R. Tunstall Taylor¹ says that the new osteoclast consists of a T-shaped base, the arms of the T being 12 inches wide and the stem 36 inches long. Arising from the intersection of the arms and on the stem is an arc 12 inches high at its summit and 12 inches wide at its base. It has the great advantage of rapidity of fracture and release, which cannot be obtained with the other osteoclasts, and it can be easily taken apart for convenience of carrying.

Hip Disease among Hospital Out-patients.—Augustus Thorndyke² presents a study of undoubted cases who applied for treatment 5 to 10 years ago at the Children's Hospital, out-patient clinic. Good results are not to be expected because of lack of care at home in applying apparatus, neglect of broken splints, straps, buckles; irregular and infrequent visits; failure to instruct parents properly, and their disgust and impatience at the long course of the disease and treatment. Fifty-five selected cases were equally divided between the sexes; 17 had disease of the right hip; 38 of the left, and 2 of both sides. In 51% the disease began under 5 years of age, in 42% from 5 to 10, and in 5% from 10 to 12. Children are not

admitted older. In estimating the duration, only those were selected who had been more than 2 years without apparatus and without symptoms. Out of 17, 9 wore splints from 4½ to 7 years, and 10 from 7 to 11 years. The tendency has been toward prolonging rather than curtailing splint treatment, a gradual leaving off and careful observation for a year afterward. Various splints and methods have been employed. Abscess came in 40%, showing that a severe form of the disease was under treatment. In 20% there was no shortening; 40% had an inch or less; 23% between 1 and 2 inches; and 17% over 2 inches. In only 5 cases was permanent flexion of the hip present of more than 40°, and in 81° the amount of flexion was less than 20°, which is considered the ideal position for a stiff hip. As regards motion, 20 had less than 20° in flexion; 8 had 45°; 4 from 50° to 80°; and 10, 90° or more, while abduction was impossible in 14, poor in 3, good or almost normal in 13. A little more than half had a good walking gait. [Author's abstract.]

Hip Disease.—R. Tunstall Taylor¹ considered hip disease, with special reference to diagnosis and the combined treatment. The writer, in a second paper, lays great stress upon the value of the röntgen ray in the diagnosis, and considers it preferable to tuberculin, in that one not only obtains an immediate picture, which cannot deceive one, whereas the tuberculin reaction if positive does not locate the disease in any definite portion of the body. Further, the röntgen ray shows the extent of the tuberculous process and in a series of skiagrams of a given case one can tell whether the disease covers a wider area or not, as time goes on. Taken in conjunction with the clinical symptoms, the author uses the röntgen ray in outlining the best treatment. This "combined treatment" he uses in cases in which it is evident that the tuberculous disease is extending, despite careful, thorough mechanical treatment. In 20 cases he used the anterior incision between the tensor vaginæ femoris and gluteus medius on the outer side and sartorius and rectus on the inner side, opened the capsule, did an erosion as indicated to be necessary in the röntgen ray, disinfected with 2½% formalin solution, introduced small wick drainage, sewed fascia and skin up as tightly as possible with silver wire; withdraws wick on fourth day and sutures on the tenth; keeps child in bed 8 weeks with traction in abduction, and uses traction splint for 6 or more months. In early cases traction treatment yields good results and in neglected cases with suppurative sinuses the combined treatment is unsafe, for fear of secondary infection, and at all events should not be expected to yield brilliant results. The immediate and ultimate results of the combined treatment are most satisfactory in properly chosen cases. The writer emphasizes the importance of cases not wearing the traction splints too long, as unduly weakening the limb and tending to bone atrophy. [Author's abstract.]

Tuberculosis of the Spinal Column, Especially the Posterior Part.—J. Wieting² discusses the conservative treatment of this condition by means of plaster jackets, and maintains that the radical operative treatment deserves wider practice than it has received. There seems to be no reason why the focus of infection should not be removed, if it is possible to reach it. Hence arises the necessity for more exact localization of the disease. A classification may be made into anterior spondylitis and posterior spondylitis. The main diagnostic points of difference are: 1. In posterior spondylitis tenderness is elicited by direct pressure over the vertebral arches and processes, while in disease of the vertebral bodies pain is produced by indirect pressure *c. g.*, pressure on the top of the head. 2. Swelling and abscess formation in posterior spondylitis always manifests itself in or near the line of the spinous processes, and is limited to the neighborhood in which the inflammation arises; while in anterior spondylitis the abscess tends to wander. The prognosis in operative treatment of disease of the arches is much more favorable than in disease of the bodies. [B.K.]

Diagnosis of Bone and Joint Tuberculosis.—K. Ludloff³ has made a röntgen ray study of tuberculous and non-tuberculous bones and joints in the very young, and has found

² American Jour. Orthopedic Surgery, November, 1903.

the following differences: The healthy femoral condyle has in its anterior part and reaching to the epicondyle, a lighter spot made up of very fine bony spicules, and fusing with the surrounding structure gradually. It corresponds with the place where the nourishing vessels enter the condyle, and is not a bone center. At the second year several long bony protuberances are seen at the inner part of the condyles, at the fourth, also at the outer part. There are usually four, and they are near the above mentioned epiphyseal spot. They disappear about the fifth year. In tuberculous knees the latter were smaller or entirely absent long before the fifth year; rough points were seen at the junction of bone and cartilage about the seventh year. On the under surfaces of the condyles, excrescences of bone form also. More bone than normal is found in all the neighboring epiphyses, and the epiphyseal spot is larger and lighter. He sees in these skiascopic changes evidences of tuberculosis, and thinks they can be utilized in the diagnosis, prognosis, and treatment of the disease. [E.L.]

Treatment of Infantile Spastic Paralysis.—Robert Jones¹ deals exhaustively with this subject. He says with regard to the degree of benefit derived from treatment that the parent should be given to understand that under favorable conditions in nursing and tuition, the child, aided by hands or sticks, will be able to walk varying distances in from 12 months to 2 years. Time and patient attention are very important factors in the treatment of the patient. The treatment should resolve itself into a system. Such a system involves operation, mechanical and educational stages. It cannot be separated into parts. If the surgeon is not satisfied that the case is to be under his control for 12 months, he will consult his reputation best by leaving it alone. Operation not followed by careful and prolonged future care give rise to disappointment and discredit. Merely dividing tendons to be followed by massage and electricity is futile and dispiriting. No opportunity should be lost of performing a tenotomy even in mild cases where a spastic tendon is felt. [A.B.C.]

Transplantation of Tendons of the Thigh.—O. Vulpus² finds transplantation of tendons in cases of quadriceps paralysis necessary only when contractures of the flexor muscles exist, thus making the erect posture difficult or impossible. Tendon transplantation in such cases assures a strong extensor muscle without weakening the flexors. The best muscle for the purpose is the sartorius, which usually escapes paralysis; sometimes it may be necessary to use one or more of the flexors or adductors. The muscles are sewed to the periosteum of the patella in preference to the tubercle of the tibia, as their attachment to the former gives them a more natural pull than when fastened to the latter. The details of 4 operations with very happy results are related at the end of the paper. [E.L.]

Sixty Tendon Transplantations.—Reichard³ reports concerning 60 tendon transplantations which he performed for infantile spinal and cerebral paralysis, Little's disease, hemiplegia, congenital and acquired deformities. He discusses his results at some length. [E.L.]

Congenital Dislocation of the Hip, and Lorenz's Method of Treating It.—J. Jackson Clarke⁴ gives a very complete account of history of methods of treatment of congenital dislocation of the hip. On page 10 an explanatory paragraph occurs that has direct bearing upon all previous reports and discussions of the Lorenz method: "The subject of the treatment of congenital dislocation of the hip, including Lorenz's method, was brought prominently before the British Medical Association in 1901. It is to be regretted that Professor Lorenz was not at that time invited to demonstrate his method at the meeting; for it is evident to those who have seen Lorenz operate that the surgeon who introduced the subject at the meeting had never really performed Lorenz's actual operation at all, and hence, though many interesting details of his experience in performing the open operation were communicated by Mr. Burghard, all his criticisms and disappointments with regard to Lorenz's treatment are of no account. For another reason the missed opportunity of introducing Lorenz's work to

the profession in this country is to be regretted; it would have forestalled and nullified the distasteful outpourings of the lay press, which were inevitable consequences of Lorenz being summoned to cross the Atlantic for the purpose of operating on the only child of a very wealthy American citizen. I am convinced that to no one can this newspaper activity have been more distasteful than it was to Lorenz, whose work was distorted and misrepresented by it." The illustrations are clear, and add very much to the description of the cases and their progress. Emphasis is given to the need of experience upon the part of the surgeon and his assistant in the selection of suitable cases, and in the feeling that yielding muscles and fascias give rise to during safe manipulation, as well as to the maneuvers that lead to reduction. Jackson Clarke, in summing up, says: "Lorenz's method of treating congenital dislocation of the hip is based on correct anatomic and physiologic grounds; it is the outcome of an exceptional experience both of open and subcutaneous; in a considerable proportion of cases it gives a perfect anatomic and physiologic result (i. e., it cures a condition hitherto deemed incurable)."

A Discussion on Congenital Dislocation of the Hip.—F. F. Burghard¹ gives a very thorough review of the above subject up to date. He says that in his own experience he has tried Lorenz's bloodless method in 30 cases; in only one of them was a perfect cure obtained, and this case was a child under 3 years of age. In the remaining 29, some were submitted later to an operation, but all of those who for any reason were not, were very much improved as to gait and general usefulness, two or three of them being so much improved that they would, in the absence of radiography, have easily passed for cured. Burghard has not followed closely either the Hoffa or the Lorenz cutting operation, but has made modifications. He has thus operated upon 13 cases. In nine the cure has been perfect, and the children are now walking about quite well; in three the head of the bone has escaped and has formed a new acetabulum above and behind the old, but the joints are quite stable. In no case has there been a complete failure. Burghard's conclusions are: 1. That all cases should be checked by radiography, and that no "cure" should be spoken of that is not a true anatomic cure. 2. That all cases of congenital dislocation in patients under 14 years should be submitted to treatment. In the great majority improvement will result, while in some a true anatomic cure is brought about. 3. That in all these cases Lorenz manipulations should be tried in the first instance. Even should they fail to effect reduction, they facilitate any subsequent procedures. 4. That the prospect of a cure by Lorenz's "bloodless method" is in direct proportion to the youth of the child, and that after the age of 4 years there is little hope of a true cure by its means. 5. That in any case the chances of a true cure by the "bloodless method" are not very great. 6. That an open operation should be done whenever a radiograph shows that the "bloodless method" has failed to reduce the dislocation, except, perhaps, in the case of a very young child—under 3 years—in whom the manipulations may be repeated. 7. That with the open operation no fear need be entertained of shock, bleeding, or sepsis. 8. That under no circumstances should the joint surfaces be remodelled. 9. That an open operation is more calculated to result in a cure, as it enables the surgeon to ascertain beyond a doubt when the head of the bone is really in the acetabulum. 10. That the open operation is especially suited for cases over 4 years of age, and for those of bilateral dislocation. 11. That after the operation the limb should be put up in the position of maximum stability; in the majority of cases this will be similar to Lorenz's position. The limb should be put up in plaster-of-paris immediately, and the casing should take in the flexed knee; this is essential in order to secure stability of the head of the bone. 12. That all tense structures should be stretched or tenotomized as a preliminary measure a week or so previous to the open operation. The after-treatment is practically identical with that of the Lorenz method. Noble Smith said in the discussion that he felt personally much indebted to Dr. Lorenz, because since seeing him operate he found he had succeeded far more satisfactorily than he had done when dependent upon Lorenz's written description. Robert Jones said until the visit

¹ Annals of Surgery, March, 1903.

³ Deut. med. Woch., 1903, No. 25.

⁴ Practitioner, March, 1903.

¹ British Medical Journal, August 29, 1903, p. 457.

of Lorenz he had no idea of the thoroughness of his manipulations, and he at once saw why so many failures had occurred in England. Since Lorenz's visit Jones has operated on 38 cases, 34 of which were reduced, as confirmed by palpation and by the röntgen ray. The statistics of the open and the bloodless methods are in the hands of the two greatest authorities, Lorenz and Hoffa, about 50% of cures. This is sufficient proof that there is considerable overlapping, and that the majority of cases operated upon by Hoffa would be simply manipulated by Lorenz. In view of the diverse opinions, Jones says he intends to persevere with the Lorenz method as a routine, operating only in the exceptional case, and after a sufficient lapse of time shall form his own conclusions with regard to the final results.

Congenital Dislocation of the Shoulder.—C. G. Cumston¹ gives a historical sketch of this affection, considers its etiology, and enters into an elaborate discussion of the differential diagnosis. The various methods of operative treatment are compared, Cumston preferring that of Duplay. He believes that excision of the head of the humerus in most cases is an unnecessary addition because the joint cavity and the head of the bone are not sufficiently changed to demand it. The capsule is practically always elongated and it is proper to resect enough of it so that when stitched together it will cover the head of the bone in a physiologic manner. A case occurring in a boy of 5 is reported. The incision recommended by Phelps was employed but was entirely unsatisfactory, the posterior incision not rendering the parts so accessible as does the anterior. The dislocation was readily reduced and the ultimate result was very gratifying. [A.G.E.]

Improvements in Extension Apparatus.—Several improvements in extension appliances in private practice are described by G. E. Gorham.² Four uprights, an inch square and 35 inches long are mortised together with cross pieces 6 inches long to form a frame not unlike an umbrella rack. To 2 of the uprights are fastened large screw hooks the position of which can be changed. These are for hanging the frame to the bed. In the 2 opposite posts are a number of holes for a pin carrying the pulley. A special foot-piece or spreader is also described. An interesting point mentioned by Gorham is that he tested the friction of the ordinary pulley and found that with an 8-pound weight the traction varied from 3 to 13 pounds, according as the leg was sliding down in bed or efforts were being made to pull it up. These figures were the average of a large number of pulleys. The point is an important one, especially in tuberculous cases where uniform traction is necessary. To eliminate this uncertainty the writer has had a simple, almost frictionless pulley constructed. [A.G.E.]

Herpes Progenitalis and Pain in the Pelvic Region Resulting from Flat-foot.—S. Ehrmann³ believes the pelvic pain in flat-foot is due to the abduction and rotation of the hip. This results in the stretching of the accessory ligaments which are inserted in the horizontal ramus of the pubis (ligamentum pubofemorale). By the rotation of the femur that part of the capsular ligament which is inserted near the ligamentum spinosum sacrum over which passes the pubic nerve becomes stretched. A hyperemia develops, and also a slight inflammation which extends to the ligamentum spinosum sacrum, and these either cause pressure on the pubic nerve or bring about an irritation of the nerve by the hyperemia of its vessels which in turn causes the herpes progenitalis. [J.H.W.R.]

Chronic Villous Arthritis, with Special Reference to Its Etiology and Pathology.—Charles F. Painter and William G. Erving⁴ report conclusions based on the clinical and pathologic study of 33 operative cases of so-called dry or hyperemic joints. The condition is always associated with hypertrophied normal synovial villi, which have undergone chronic inflammatory and degenerative changes in varying degree. It may follow joint-strain or trauma, an infectious process in the joint, especially tuberculosis and gonorrhea, or general diathetic disease, such as rheumatoid arthritis, and less often, osteoarthritis. The knee is the joint most affected. The condition is usually chronic, associated with recurrent synovitis and mild

joint swelling; relief by rest, and lacking the symptoms of an acute arthritis, pain is not common. There is tenderness localized over the fringes, and a sensation of instability of the joint on use. Conservative treatment consists of strapping the joint, correction of flat-foot or other causes of joint-strain, local stimulating bathing, and general tonics; these failing, removal of the fringes to be considered. The arthrotomy should clearly expose the interior of the joint—best in the knee by 2 incisions parallel to the patella tendon—and the fringes should be dissected out as far as possible, trusting to subsequent scar formation to prevent recurrence. Drainage usually unnecessary; complete or partial fixation until removal of stitches should be immediately followed by active and passive motion, fomentations, etc. The prognosis in uncomplicated local conditions is excellent; when part of a general condition, such as rheumatoid, treatment is at best but palliative. [Author's abstract.]

The Foot of the American Negro.—Albert H. Freiburg and J. Henry Schroeder.¹ Herz and Muskat, having shown that flatness of the plantar arches of the aboriginal negro is not a racial characteristic, 88 feet of adult negroes and 40 of children were examined. Conclusions: (1) Flattening of the arch is much more frequent in the American negro than in his white neighbor; (2) the same is true of hallux valgus; (3) the well-arched foot occurs in the American negro with sufficient frequency, however, to establish it as the normal; (4) normal feet preponderate decidedly in negro children, although flattening is more common than in the white; (5) the flat-foot of the adult negro has, therefore, developed after childhood in the greater number of cases; (6) the deforming effects of foot wear are much more evident than in the white of the same class; (7) The length of the negroes heel and the width of his forefoot may explain the deforming action of foot gear designed primarily for the feet of whites. [Author's abstract.]

Treatment of Hallux Valgus.—W. Thomas² describes what he calls the "tomato splint," which has proved of great value in his hands. It is made of dentists' vulcanite, aluminum, wood, brass, celluloid, or any other nonirritating material. The posterior border is concave and rests against the heads of the metatarsal bones. The upper surface has 3 grooves for the middle toes, and 2 half grooves for the great and little toes. Between the grooves are septums, the one between the great and the next being higher than the others. The septums are pierced so as to allow the strapping by which the splint is fixed to pass through. It may be worn at night inside a stocking; in a slipper or loose shoe during the day. Properly applied, and regularly worn it brings some of the most distorted toes to the normal condition. [H.M.]

Polydactylism of the Feet.—H. Haberer³ reports a case of this anomaly occurring in a boy 17 years old. Beside the normal 4 toes on the right foot there were, in the place of the big toe, 2 toes united by a web, which articulated with a common metatarsal bone. Beside this double toe there was on the inner side of the foot a supernumerary toe with 3 phalanges, 1 metatarsal bone, and 2 toe-nails. There was also a scar on the median surface of the toe showing where a supernumerary toe had been removed when the patient was 7 years old. The paper is illustrated with röntgen ray photographs. [J.H.W.R.]

The Pathology and Treatment of Hallux Rigidus, Hallux Flexus, and Hallux Extensus.—A. H. Tubby⁴ believes that one cause underlies all of the above conditions—namely, an osteoarthritic condition of its first metatarsophalangeal joint. In moderately painful cases attention to the size and shape of shoes. In severely painful cases excision of the head of the metatarsal bone is required. It is preferable to interfere as little as possible with the base of the first phalanx.

Phelps' Operation for Club-foot.—E. Muirhead Little⁵ speaks of 2 classes of cases of club-foot in which he has tried Phelps' operation: 1. Those of such severe deformity that careful and persistent treatment by milder methods has failed to effect a complete cure, despite all the care of the surgeon and the patient's friends. These I would call cases of necessity. 2.

⁵ British Medical Journal, October 17, 1903, p. 977.

Cases chiefly in hospital practice, which, owing to the poverty or indifference of the friends, are neglected as regards after-treatment and relapse again and again. These I would call cases of expediency. Little has used Phelps' operation in 27 cases, and gives illustrations of the results. He has adopted a modification which he believes to be of advantage in dividing tendo-achillis last, and in the manner of making the skin flap, after the suggestion of Harding Frieland. He refers to the fact that unknown to each other, and at about the same time, Dr. Jonas, of Omaha, had recommended the wedge-shape skin flap. Little does not put the foot in plaster cast immediately after the operation, but waits until the oozing has ceased. Twenty-seven operations were performed on 20 patients. The ages ran from 2½ years to 16 years. Only 3 were under 5 years. The immediate results have been in all cases good, and the later results, as far as ascertainable, were most satisfactory to the patients. The form of the foot has in many cases not been ideal.

The Substitution of Temporary and Absorbable for Permanent and Unabsorbable Sutures in the Operation on Bone.—R. H. Anglin Whitelocke¹ says metallic sutures are more likely to cut their way out. In many cases the system of wiring is an over-elaborate and unnecessary detail. The use of ordinary catgut or kangaroo tendon has been most satisfactory. The favorable results obtained by these absorbable sutures should increase the number of cures of bone injury that are treated by free incision and suture.

THE PUBLIC SERVICE

Health Reports.—The following cases of smallpox, yellow fever, cholera and plague, have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended February 26, 1904:

SMALLPOX—UNITED STATES.		Cases	Deaths
California:	San Francisco.....Feb. 7-14.....	5	
District of Columbia:	Washington.....Feb. 13-20.....	6

Laboratory case.

Changes in the Medical Corps of the U. S. Army for the week ended February 27, 1904:

HUGHES, LEONARD S., contract surgeon, leave granted October 22 is extended one month.

MCANDREW, First Lieutenant PATRICK H., assistant surgeon, now on temporary duty at Fort Des Moines, Ia., will join his proper station, Jefferson Barracks.

GIRARD, Colonel ALFRED C., assistant surgeon-general, having reported his arrival at San Francisco, Cal., will report to the commanding general, department of California, for duty as chief surgeon of that department, to relieve Lieutenant-Colonel George H. Torney, deputy surgeon-general. Lieutenant-Colonel Torney will report to the commanding general, department of California, for assignment to the command of the United States General Hospital, Presidio, to relieve Major William P. Kendall, surgeon. Major Kendall will proceed to Ord Barracks, Cal., for duty.

WATERHOUSE, First Lieutenant SAMUEL M., assistant surgeon, is relieved from duty on the transport Logan and from further duty in the Philippine Division, and will proceed from San Francisco, Cal., to Fort Worden, Wash., for duty.

VOORHIES, HUGH G., contract dental surgeon, now on temporary duty at Plattsburg Barracks, is relieved from further duty at San Juan, P. R., and will report for duty at Fort Hancock.

PATTON, First Lieutenant IRVINE W., assistant surgeon, leave granted January 21 is extended one month.

NICODEMUS, FRANK O., sergeant first class, Fort Sheridan, will proceed to Manila, P. I., about March 1.

GWINN, ARTHUR C., sergeant first class, upon arrival at Fort Sheridan with the Twenty-seventh Infantry, will report for duty at that post.

PATTON, First Lieutenant IRVINE W., assistant surgeon, now on leave at Huntsville, Ala., is relieved from further duty at Fort Hamilton, and will proceed from Huntsville to New York City and report for duty as surgeon on the transport McClellan.

WATERHOUSE, First Lieutenant SAMUEL M., assistant surgeon, is granted leave for two months.

GREENE, EARL F., sergeant first class, Army General Hospital, Washington Barracks, will proceed to New York City and report for duty aboard the transport McClellan.

Changes in the Public Health and Marine-Hospital Service for the week ended February 25, 1904:

STONER, G. W., surgeon, four days' leave of absence from February 24, 1904, under paragraph 189 of the regulations.

ANDERSON, J. F., passed assistant surgeon, granted leave of absence for two days from February 18, on account of sickness—February 24, 1904.

STANSFIELD, H. A., assistant surgeon, to report to chairman of examining board at Washington, D. C., March 9, 1904, for examination to determine his fitness for promotion to the grade of passed assistant surgeon—February 25, 1904.

McCLINTIC, T. B., assistant surgeon, to report to chairman of examining board at Washington, D. C., March 9, 1904, for examination to determine his fitness for promotion to the grade of passed assistant surgeon—February 25, 1904.

BERRY, T. D., assistant surgeon, directed to rejoin station at Louisville, Ky., upon return of Surgeon G. M. Guiteras—February 19, 1904.

HERTY, F. J., pharmacist, granted leave of absence for four days from February 14, 1904, under paragraph 191 of the regulations.

Promotions.

Passed Assistant Surgeon H. D. Geddings commissioned as surgeon, to rank as such from November 23, 1903—February 12, 1904.

Passed Assistant Surgeon C. P. Wertenbaker commissioned as surgeon—February 16, 1904.

PUBLISHED WEEKLY AT 1321 WALNUT STREET PHILADELPHIA BY THE AMERICAN-MEDICINE PUBLISHING COMPANY

VOL. VII, No. 11.

MARCH 12, 1904.

\$5.00 YEARLY.

The criminal use of physicians' names is becoming more and more common. Koch has been compelled to warn even the medical profession of America that the use of his name by firms of charlatans in many of our larger cities was of course unauthorized, and in spite of all the attempts of himself and friends to prevent it legally. Recently a wellknown physician found that a chemical manufacturing firm was using his name for the wide exploitation of a method of cure advertised as if backed by the scientific ability and reputation of the physician. Even if the legal injunction will be at last successful, there is the delay, the harm to the reputation, and the expense, for which there is no reparation. A similar wrong is the unauthorized republication of the papers, clinical reports, etc., of physicians by manufacturers of drugs, makers of instruments, etc., all in a manner to deceive the incautious reader and make him think the original writer has permitted the use of his name in this way. To such proportions have these abuses grown that the profession must be on the alert to meet the criminals with the law. One would suppose that the terms of the statutes already enacted against such plain intent to deceive would be sufficient; but if not we should secure the passage of such specific laws as will prevent repetitions of the offense.

The Breaking-up of the Long Winter.—The reports from all northern large cities of the United States show an alarming increase in the number of deaths from pneumonia. In New York all pneumonia death records for a decade are shown to be broken by the Health Department report for last week, which recorded 1,800 deaths, 460 of which were attributed to pneumonia. For the corresponding week of last year there were 1,479 deaths, 303 due to pneumonia. The increasing prevalence of the deathrate from infectious pneumonia is recognized also by the State Health Department in its monthly bulletin by the announcement that hereafter it will be given a separate column in the bulletin and be the subject of distinct notice. The total number of deaths from pneumonia in the State during January is given at 1,510. The long contention of the Chicago Health Commissioner is being substantiated, and his suggestions heeded. Not only is the pneumonia deathrate increasing, but the general deathrate also, due to the greater prevalence of small-

pox, typhoid fever, and other infectious diseases. Is this due to the long, severe winter, with the resultant lessening of vitality, and the closer herding together of the poor for warmth? Vast quantities of filth have been gathered in cities, and as Spring breaks and ice and snow melt and are being washed away, may we not expect a still greater mortality? Health Boards should exercise redoubled vigilance to prevent the calamity, and the cooperation of every householder and citizen is of the greatest importance.

The blessing of anesthesia is commonly thought to concern only the patient. To free him utterly from the awful agony of a major surgical operation was, of course, the chief and striking glory of the discoverers of anesthetics. But one is likely to forget that there are other results of more real benefit to the world which follow inevitably though more indirectly. The first of these is the vast progress anesthesia has made possible in laboratory research. Operations and experiments on living animals would not have been possible in the olden times that are common now, men could not have been found in sufficient number and with the requisite insensitiveness to carry on the experiments necessary without anesthesia. The present freedom of animals from suffering would enable even the mythical fiend of the antivivisection's imagination to do his work more easily and better. In the second place, anesthesia during surgical operations has been a not negligible cause of the establishment of the nursing profession. Women could not have been found to help the surgeon under the old conditions. Thirdly, anesthesia has enabled the profession to do away with the former absolute necessity of the utmost quickness in operation. The result was a haste that made the best operations impossible. The mortality of anesthetic operations must be a hundred times better than when the patient writhed and begged for mercy.

Errors in the diagnosis of smallpox, as all physicians know, are too easily made even when the best knowledge exists and the best precautions are insured. But when such knowledge and care are replaced by ignorance and thoughtlessness, sometimes wilful, and perhaps even malicious, the prevention and detection of the disease become all the more doubtful. The spreading of the germs by tramps, by traveling workmen, by

those with nitric acid scars, the herding together of laborers by public works contractors—all aided by the ease of intercommunication which today exists—these and many such causes tend to make fresh outbreaks a matter of daily record: There is also a lukewarmness of belief on the part of some medical sects, as to the value of vaccination, which is really a greater danger to the community than the stupid malevolence of the hordes of the antivaccinationists. Hospital physicians should be especially alert not to make errors of diagnosis. In last Tuesday's *Ledger* occurs the following paragraph:

Blanche Smith, a nurse in St. Luke's Homeopathic Hospital, who, with Barbara Frey, another nurse, contracted the disease after nursing Thomas Wilson, a boy, who was suffering from smallpox, but whose illness had been diagnosed as typhoid fever, died yesterday in the Municipal Hospital. Mrs. Lizzie Wilson, the mother of the boy, who contracted the disease after the death of her son in St. Luke's Hospital, died on Sunday at her home, 2630 Bancroft street.

State Responsibility in the Protection of Water-supplies.—It would seem that public effort can only be enlisted in the protection of human life by the periodic recurrence of great disasters. It is the old story of the stolen horse and the careful barring of the empty stable. The history of the two terrible outbreaks of typhoid fever during the past eight months has left an indelible impression on the memories of some; to others it is a mere haze upon a horizon of indifferentism. Before it is entirely gone, however, let us see what is the probability of its repetition.

Most States of our union have found it necessary to make some definite provision against these terrible scourges, and where the idea of prophylaxis has been conscientiously carried out remarkable results in the way of immunity have been obtained. And let us say that while typhoid fever is the type of disease most commonly occurring as a result of the ingestion of impure water, there are other diseases quite as derivable from this source, though less noticeable because they are more sporadic and less epidemic in natural characteristics. According to Mr. C. C. Brown, a prominent engineering expert, Indiana has the most defective laws of any State as regards the control of a pure water-supply. The lower courts of that commonwealth have decided that natural bodies of water are the natural recipients of sewage, and it would seem that the higher courts have acquiesced in that opinion. The Secretary of the Indiana State Board of Health is doing all he can to get proper legislation in the matter, and he has established a series of lectures upon health subjects to be given before the authorities by men of experience; and it was in this capacity that Mr. Brown made his assertion. Streams in the State are absolutely without protection; small watersheds are bordered by scattered houses, sewage from which is pretty sure to reach the water-supply; and the drainage of the city of Indianapolis into the West Fork of White river is actually so noxious that no fish can live in it. We are not told whether any drinking water comes from White river, presumably not, for good fortune would hardly be so propitious as to grant the remarkable immunity from epidemics that Indiana now seems to enjoy were that the case.

In Pennsylvania there is some control, but it is said to be less than that of New York State, and also that existing laws are less in force than is the rule there. However this may be, there was certainly a lack of the executive power at Ithaca, for it has been proved that the epidemic among the students and townspeople there was due to a careless and accidental pollution of the immediate watershed of the city reservoir. According to Engineer C. C. Vermeule, if our neighbors in New Jersey succeed in putting through their gigantic sewer into Newark Bay, New York City will suffer, and suffer horribly for her generosity in allowing it. This opinion was maintained, in spite of no end of contrary evidence furnished by those who wished to make our confines a dumping-ground for the accumulations of filth from a neighboring city.

The means of getting pure water are two in number. One is to keep it pure, the other is to pollute it and then purify. In the language of Professor Geddes of Glasgow: "At first we try to purify the river, but later it dawns upon the authorities that it would be simpler and even cheaper to stop polluting it." Of course everybody knows that it is impossible to establish or to maintain bacterial purity in any large reservoir and if pathogenic germs are excluded it is certainly unnecessary; but care should be taken in this regard to find out what kind of germs we have to deal with. Filtration is an old and in some respects an inadequate method, especially if relied on too implicitly. In Paris they are purifying the waters of the Seine by electricity. Air is ozonized between two rapidly revolving electric cylinders and is then mixed with the impure water, thus quickly oxidizing all organic matter. It is said that "the water comes away more sparkling and purer than that from a mountain spring." But many things are possible in Paris that Americans have not been able to equal. In regard to the fixation of responsibility upon State officers *Municipal Engineering* says: "The occurrences at Ithaca and Butler show negligence which, in the former case at least, in face of the possibilities of control, was almost criminal, and show that good laws are of no avail without intelligent supervision of their enforcement by the responsible local authorities." There is no doubt that a time will come, when through intelligent prevention, epidemics of every sort will be unknown throughout the entire United States. It seems unfortunate, though, that the millennium is so slow in coming when it is so badly needed.

Hospitals for Chronic Diseases.—It is a remarkable circumstance that while donations are bestowed to equip hospitals for general and special diseases, nobody seems to have given a thought to the necessity for hospitals for chronic diseases. There certainly are homes for chronic invalids, there are institutions for incurables, and every large city has a dumping place for outcasts, but there are no hospitals for the cure of chronic affections, with the exception of those for tuberculosis and cancer, which latter are by no means the most important cases from a medical point of view. On the other hand, it can easily be understood that hos-

pitals for chronic diseases could not very well have been established at a very early period, considering that in former times our pathologic and therapeutic knowledge was so limited that many of the chronic affections were looked upon as incurable, and also considering that in former times the social and humanitarian education of the people did not particularly favor the establishment of hospitals, and finally that the financial conditions were not nearly as favorable as they are at the present time. All this is changed then for the better, and circumstances have assumed such a totally different aspect that the establishment and endowment of hospitals for chronic diseases might well be thought of. Attempts have been made to overcome the lack of such accommodation by providing sanatoriums, but these are generally situated outside the cities, and at the best are only available for the financially favored. The physician is positively at a loss where to send his poorer patients who suffer, let us say, from a chronic renal disease or a chronic disorder of the stomach. They will find no room in any of our hospitals, unless an acute exacerbation happens to supervene simultaneously, but as soon as the acute condition is cured, the patient will have to quit the hospital, even though he may be unable to work. The very nurses get tired of chronic patients, nor is there any training of nurses for the care of chronic patients. Even if the patient is transferred to a "home," he will have little or no chance of enlightened medical treatment. It is also a deplorable fact that in these so-called "homes" there is hardly ever any rational medical treatment, and thus it is easily understood that the case of a patient who once enters one of these homes is synonymous with "incurable." Every big city, or at least every State, ought to have a hospital endowed by public funds or private charity, in which all chronic, noncommunicable, but curable diseases should be rationally treated. There is plenty of provision made for typhoid fever and appendicitis, and it is time that we should direct our attention to the rational hospital treatment of diseases, more or less chronic in character.

Dress Reform for Men.—The question of reforming men's dress may be looked upon from at least four different sides. There is the humorous side, the practical side, the ethical side, and last, but not least—the hygienic side. The humorous fiber has been well supplied recently by the Dressmakers' Association of the United States, which solemnly conclave at Atlantic City under the auspices of the Merchant Tailors' Association. The dames demanded that men should wear nice lace collars and ruffles and fancy buckles and silk breeches, in fact, that they should dress up as people did in the times of Schiller and Goethe. A plea with these ladies on the part of a mere male member of the assembly that, after having appropriated everything else from the horrid sex, they might at least leave them their trousers, went unheeded. The ethical aspect of men's dress may, in these practical and enlightened times, be relegated to a well-deserved back seat. Let common sense come first. Schiller and Goethe are dead anyway, and let us hope that the men who liked to dress in feminine bau-

bles are dead also. Perhaps they did not even like it, and had to give way to some forerunner of the Dressmakers' Association of the United States. But as dead men tell no tales, there is no knowing. That a dress reform for men from a practical and hygienic point of view is badly needed, there is no doubt. What can be more ridiculous than cutting the front of vest and coat away and thus expose chest, lungs, throat, etc., to the inclemency of the weather, giving rise to serious illness? What sense is there in constructing the back of a vest with a mere, thin lining? Do tailors imagine that the spine requires less protection than any other part of the body? What practical use is there in wearing collars high enough to outshade the old-fashioned "father-murders," collars that prevent the free movement of head and neck, and tight enough to seriously interfere with the proper function of several organs? It is ignorance, pure and simple, and it is one of the physician's duties to enlighten the public on the necessity of considering their health before fashion, ignorance, and folly. Wherein male attire fails is the even distribution of protective warmth. One part of the body should be as warm as the other. But not enough that the present style of dress makes this an impossibility, to flatter men's vanity (presumably), tailors have acquired a habit of padding the coats "to improve the figure," and thereby introduce another element of unequal distribution of protection. As a proof of how little men care about this "improvement," it may safely be stated that nine men out of ten do not know where their coats are padded, or that they are padded at all, and then they wonder why in a biting wind they should feel cold in one shoulder and not in the other. If physicians called the serious attention of men to these anomalies in their clothing and inculcated in them correct hygienic principles of dressing, they would take a great step in the direction of preventing disease.

Physicians and the Commonwealth.—It is a matter of public concern to analyze the presumable public conduct of an aspirant for political honors, and, as a rule, that forecast will not be far wrong if it is gauged by the leading business principles which are known to guide such aspirant in the pursuit of his daily vocation, or, as Sterne has it, "Inward sincerity will influence the outward deportment; but where the one is wanting, there is great reason to suspect the absence of the latter." That is the part of the life of the individual which comes in contact with the outer world, and it is but fair to assume that a merchant or lawyer who is in the habit of conducting his business in a fair and straightforward manner, will be actuated by the same principles when entering upon a responsible, public career. From this point of view it is of importance that the medical profession in all parts of the country should scrutinize the contents of newspapers whose editors or publishers nourish high political ambitions, but whose business morality is not of the highest order, newspapers that often play the role of seducers rather than of teachers and educators of their readers in regard to matters of health and medical treatment. The medical profession should take these "latter-day saints"

seriously to task; the following is a letter which a New York physician recently addressed to the editor-publisher of four or five newspapers whose specialty it appears to be to contradict by the paid advertisements what he is advocating in the editorials, thus illustrating the bewailable, modern tendency of "not doing what you preach." But let the letter speak for itself:

NEW YORK, November 12, 1903.

Dear Sir:—I have read with great interest a number of editorials in the ———, particularly those which pertain to the sociologic, philosophic and national problems. Their pervading spirit seems sound and plausible, means progress, tends to the enlightenment of the masses, and is certainly far superior to that of any other daily newspaper in this or any other country.

However, if you wish to be a great moral teacher, if you wish to be the exponent of social morals, and if you entertain the pardonable ambition of sitting in the Presidential Chair in Washington, you will in common decency—to say the least—have to turn your attention to the advertising columns of your papers, for the high spirit expressed in your editorials is certainly not reflected at all in the space devoted to the announcements. Your journals, on account of their superior editorial matter, reach homes, and the advertisements which reach those homes simultaneously must certainly call forth embarrassment and indignation. If you want to be a great moral teacher and the liberator of the lower classes from preconceived notions, you must see that advertisements which bear the stamp of deceit, humbug and immorality, be excluded from your publications. The restoring of lost manhood, the curing of venereal diseases in 10 days, the sure production of the monthly flow, the providing of a retreat for ladies in interesting circumstances, are certainly not the domain or the office of a moral reformer. Not only are advertisements of this kind objectionable in themselves, but they are productive of great moral harm by acquainting innocent young girls, for instance, with the fact that there are people who make it their business to remove incipient gestation. If some other paper lays itself out for announcements of this description, that paper will be known accordingly, and men will take good care to bar its way into their homes. You, however, are not on the same level with them; you stand upon a public platform, aspiring to high honors, and you cannot afford, therefore, to be the means of carrying immorality into decent families. Nor can I assume that the small financial gain would prompt you to continue the insertion of these objectionable announcements, especially as there are other papers which rigidly exclude them.

To this letter no answer was received; comment superfluous.

New Hospital at San Juan.—Information, under date of February 27, says the First Presbyterian Hospital on the island was opened today with appropriate ceremonies. The hospital cost \$20,000, which was raised in New York. Governor Hunt delivered an address.

Foreign Bodies in the Abdomen.—An exchange comments editorially as follows: A case of this kind has provided one of the latest sensations in Italy, where, for the third time in the history of the Parliament, the Senate has been sitting as a High Court of Justice to try one of its members on a criminal charge. The accused is a wellknown surgeon and Senator, Professor Dantona, who is charged with culpable homicide in having caused the death of a patient by negligence. The victim, a certain Signor Jammurino, was operated on by Professor Dantona for an internal complaint. A month later, after his return to his family, Signor Jammurino suffered a sudden relapse and died. A local physician made a postmortem examination, and declares that he found in the body a large piece of gauze, presumably left accidentally in the wound, which was responsible for the formation of the abscess which was the immediate cause of death. Professor Dantona, in his defense, declares either that the gauze was not found as the prosecution asserts, or that if it was found, its presence must have been due to the dressing of the wound subsequent to his own attendance on the patient, and to the carelessness of some subordinate.

AMERICAN NEWS AND NOTES.

GENERAL.

The Cystoscope.—March 9 was the twenty-fifth anniversary of the first demonstration of the cystoscope by Prof. Max Nitze, of Berlin. On that day the admirers of Prof. Nitze, in Germany, celebrated the event, and a number of American physicians, through a committee in New York, sent a congratulatory telegram to Prof. Nitze. It read as follows: "Prof. Max Nitze, Berlin. Your colleagues and pupils congratulate themselves and the profession on the twenty-fifth anniversary of the demonstration of the cystoscope."

The National Association for the Study of Epilepsy held its third annual meeting in Philadelphia in November, 1903, and on March 1, 1904, issued a memorandum setting forth the purposes of the Association. This in part says: At the Philadelphia meeting the Association discussed its inability, for the lack of money, to do more valuable work in the way of disseminating literature bearing upon the public care of the epileptic and the study of his disease, and after full discussion, it was unanimously decided to require a membership fee of \$5, annually. The Association is exceedingly anxious to help secure public care in some form for the epileptic, in every State in the Union. At present 7 States only have made such provision. They are: New York, Massachusetts, Ohio, Pennsylvania, New Jersey, Kansas and Texas.

A New Poisonous Drug.—A more powerful poison than any heretofore known is now being investigated. Mr. Lascellus Scott, of England, has recently published some startling facts about cyanid of cacodyl. It is a white powder, melting at 33° and boiling at 140°, which when exposed to air gives off a slight vapor, to inhale which is death. Its effect is so powerful that Mr. Scott states that he has seen one-millionth part of a grain of the drug instantly kill 4 dogs when they were introduced into an air-tight cage with it. While but little known, it was made many years ago by a noted French chemist, Cadet. He combined potassium acetate with white arsenic, producing a fuming liquid, oxid of cacodyl. This, when combined with cyanogen, a radical of prussic acid, produces cyanid of cacodyl, thousands of times more poisonous than the pure prussic acid. —[*Albany Medical Annals.*]

Study of Leprosy.—From Honolulu comes the news that Surgeon-General Wyman, of the United States Marine-Hospital service, has invited Dr. Charles B. Cooper, of the Board of Health of Hawaii, to become chairman of a committee to undertake an exhaustive investigation and study of leprosy. The other members of the proposed committee are Dr. J. F. Smith, secretary of the Superior Board of Health of San Juan, Porto Rico, and Dr. J. C. Nolte, of the State Board of Health of Louisiana. This committee is to suggest lines of investigation to competent observers willing to undertake the work. The committee is also to collate the results of experiments and observations made in connection with its work, and to report at suitable times on the advance in knowledge in regard to leprosy. The Board of Health of Hawaii some time ago formulated a plan for the systematic study of leprosy at the settlement of Molokai. The plan included a request for an appropriation from Congress for a suitable provision for a bacteriologic laboratory at the leper settlement, and for residences for investigators. The Territory of Hawaii would provide maintenance and assistance, and an invitation would be sent to the leading institutions and societies in the world which provide for original research into such subjects, to send capable investigators. By this means, it was thought, the best field in the world for the study of leprosy would be made available for scientific study.

Education of the Public against Spitting.—The Bulletin of Chicago's Health Department, for the week ended February 27, quotes from a leaflet, on the restriction and prevention of pneumonia, recently issued by the Michigan State Board of Health, as follows: "Legal measures it is obvious can be used only against the person spitting in public places. The person who contaminates the air of his home with his saliva is largely beyond the reach of such measures. Public opinion is necessary to sustain the enforcement of any law. It is especially necessary where it is sought to enforce a law depriving citizens of a privilege they have long enjoyed and can see no reason why they should not continue to possess. Education of the people concerning the importance of destroying or disinfecting all sputa must, therefore, precede forcible measures. This education should be such as to induce every intelligent person to destroy or disinfect the sputa or saliva he or she ejects, and to insist that the careless and the ignorant be compelled to do likewise. It is to be hoped that such education will result in the formation of public opinion so that it will demand that the law shall not only reach the public spitter, but he, also, who contaminates his own home, thus not only endangering his own family, but also endangering the lives of all who may enter such a home. The press, the teachers in our public schools, the preachers in our pulpits, and all others who in any degree mold public opinion should urge the most important sanitary reform."

Achievements of American Medical Men.—Dr. Roosa, in a recent address in New York City, at which he was the guest of honor, summed up briefly the important discoveries of American physicians. In part he said: In the Massachusetts General Hospital was first found out an anesthetic to quiet the pains of women in their most agonizing period of existence; of men and children suffering under the knife. In America the first great operation upon a hitherto incurable disease of the female sex was first successfully adopted by a Kentucky surgeon, and in America the first exact knowledge of that disease which carries off so many men was first made known by a New York surgeon. And in America, first of all, another large class of cases, passed from the irremediable to those that were perfectly cured, and the statue of the man who did all this stands behind a new library on Bryant Park—a man who began work in Alabama, and expanded it in New York. The lifegiving method of intubation was first taught by a New York post-graduate professor.

Miscellaneous.—**Colorado Springs, Col.:** Dr. William C. Sturgis, formerly mycologist of the Connecticut Agricultural Experiment Station, has been appointed lecturer on botany at Colorado College, Colorado Springs.—**Cambridge, Mass.:** Dr. Charles S. Minot, of Harvard Medical School, and Dr. Franklin P. Mall, of Johns Hopkins University, have been made members of the commission for Neurological Research, appointed by the International Association of Academies.—**Foreign:** Edinburgh University will confer the honorary LL.D. on Dr. Alexander Macalister, professor of anatomy at Cambridge, and on Dr. Hannis Taylor, professor of constitutional and international law at Columbian University; St. Andrews University will confer the degree of LL.D. on Dr. J. N. Langley, professor of physiology at Cambridge University; The French Geographical Society has awarded its great gold medal for 1904 to Sven Hedin, the Swedish explorer; The new Laboratory of Hygiene in the University of Jena was dedicated on January 24.—**Chicago:** Dr. Nicholas Senn, of Chicago, has been elected a member of the Swedish Medical Association.

NEW YORK.

New Home for Nurses.—The Bellevue Training School for Nurses has bought, for about \$50,000, property and will erect thereon a six or seven story building, to be used as a training school and nurses' home. The school heretofore has been quartered in some three and four story buildings on Twenty-sixth street, immediately at the rear of the site just purchased. These old structures will be used in connection with the new building, and it is said that the latter may eventually be extended over the entire property.

Would License Optometry.—There is a bill now before the Legislature of New York, which, if passed, will legalize optometry in its application by laymen as well as physicians. It is required, however, before one can practise the art of fitting glasses, that he shall pass an examination by a regularly appointed board of optometry under State supervision. Many physicians in the State are enlisted in a fight against the bill. A similar measure was advocated 8 years ago. In the former instance, however, the bill did not make provisions for a State Board of Optometry, as does the present proposed law.

Night Dispensary Service.—The New York *Sun*, commenting upon this subject, editorially, says in part: "On this account the trustees and medical staff of the New York Polyclinic Hospital, at 214 East Thirty-fourth street, have instituted a night dispensary service for the benefit of those who are not able to pay physicians, and who by reason of their employment during the day are prevented from seeking relief at the various day clinics. In inaugurating this service it is especially the intention to aid the large number of deserving young women employed in the various department stores and manufactories, who otherwise would be unable to secure needed medical attention.

New St. Francis Hospital.—The Sisters of the Poor of St. Francis, who for 38 years have conducted St. Francis' Hospital, are erecting a new hospital directly opposite St. Joseph's Hospital for Consumptives. There will be 19 large wards, giving space for 304 beds, and 40 small wards, a number of which will be used for private patients. In addition, there will be constructed a house for the sisters, 120 by 54 feet, the lower floors of which will contain the kitchens and storerooms and a handsome chapel, 48 by 80 feet. There will also be a garden for the patients. The hospital will be practically free to all patients, and as the expense of its erection is great, the help of the public is invoked to aid in the undertaking.

Changes in Albany Hospital Staff.—Among the changes recently made in the staff of the Albany Hospital of special note is the appointment of Dr. Albert VanderVeer as surgeon-in-chief. This is a new position created by the Board of Governors in order to retain the services of Dr. VanderVeer in the general management of the hospital while acceding to his wish to retire as attending surgeon. The appointment is a commendable recognition of a long and honorable service to the hospital. Dr. William Hailes has resigned as attending surgeon and has been transferred to the consulting staff. Drs. Edgar

VanderVeer and Arthur Elting have been made attending surgeons, and Dr. Arthur Sautter assistant attending physician in the department of diseases of the skin.

Newspaper Objects.—According to a New York exchange, a bill recently introduced by an assemblyman will, if it becomes a law, prohibit after May 31 next the publication by any newspaper or other public periodical, except medical or surgical journals, of "any picture, device, or representation of one or more man, woman, or child, or of the features or any part or parts of the human body in connection with or as part of any advertisement of any patented medicine, drug, or surgical instrument." "This," says the exchange, "is a particularly nonsensical and absurd piece of lawmaking, if it is not something worse, and for it there seems to be nothing that even remotely approaches a necessity. Legal protection already exists against the unauthorized use of personal portraits that results in measurable damage to reputation, and if people who think they have been benefited by heterodox medication are willing, out of gratitude or for a consideration, to let the makers of the preparation publish their pictures in an advertisement, there is no obvious reason why the medical papers should monopolize the business." It is very obvious that the newspaper in question is viewing the matter only from the "pecuniary" standpoint.

PHILADELPHIA, PENNSYLVANIA, ETC.

Nurses Start for Japan.—Dr. Anita Newcomb McGee and eight other Red Cross nurses left recently for Japan, where, at the instance of the Philadelphia Red Cross Society, they will serve the Japanese Government.

Typhoid Increases.—Typhoid fever and pneumonia prevail to an alarming extent, according to the official health report. It shows 195 cases of typhoid fever for last week, which is an increase of 47 cases over the preceding 7 days. There were 116 deaths from pneumonia. Physicians say pneumonia is in every ward in the city, while typhoid fever cases are reported from 39 out of the 42 wards. Deaths from all causes numbered 628, a decrease of 65 compared with the previous week. In view of the present increase, the officers of the Board of Health express a fear that an epidemic of typhoid fever in the city is imminent.

Cancer Hospital in Need of Aid.—The Cancer Annex of the Philadelphia Home for Incurables has become entirely inadequate for the demands which are made upon it. This is the only place of its kind in the State for such sufferers above the pauper class, and men who are unable to gain admittance to it are compelled to remain in their own homes for treatment. The managers of the institution have determined to erect an additional building for men who are afflicted with cancer, and they have sent out an appeal for funds wherewith to make the improvement. The Philadelphia Home for Incurables is not a rich institution. Without aid from the State and with a very small endowment fund, there is great need of additional income. The place is always full and the waiting list is large.

Hospital Cars for Pennsylvania Railroad.—Officials of the Pennsylvania Railroad Company have authorized the construction of 4 hospital cars for the company's use in the event of accidents. The hospital cars will be stationed at division terminals, and in case of a wreck will be hurried to the scene and take care of the injured. The cars will be fitted up with beds and all the necessary instruments and appliances for treating patients. They will be kept in readiness for service at any time during the day and night, and when dispatched to the scene of accident will be accompanied by trained nurses and physicians to whatever number will be required. Recently the company authorized the installation of first aid to the injured boxes to be placed on all the cars and in the various stations and shops. The boxes contain bandages and such medical supplies as are necessary for emergency cases, with printed directions showing the employees how to use them. The trainmen will also be instructed by the medical officers in the proper use of the different articles.

Birth Certificates Should be Supplied by Parents of School Children.—Acting upon a suggestion to the Committee of Compulsory Education by Captain William Thornton, chief of the bureau, the Board of Education will probably decide that parents, when entering their children in school for the first time, will also present a certificate telling the date and place of the child's birth. This certificate, it is suggested, must follow the child through its school career, the same as a certificate of vaccination. The result will be that there will be less inclination on the part of parents to make false statements concerning the age of the child in case they desire it should go to work before it reaches the age required by law. During the year there were 1,203 parents notified of the requirements of the law concerning their children. Of 103 parents prosecuted, two refused to pay the fine and were sent to prison. The attendance officers reported and investigated 42,115 cases from schools during the year and their census of school children between the ages of 6 and 16 years showed the number to be 212,308.—[Philadelphia Press.]

Births Not Reported.—Commenting upon the recent activity of the coroner and police authorities in discovering a band of criminals engaged in "baby farming," the *Philadelphia Press* says, editorially: Nothing will ever be accomplished until the lax laws now existing in regard to the registration of births, private lying-in hospitals, the care of babies and their disposition are replaced by adequate legislation. Today it is altogether probable that from 5,000 to 8,000 births are nowhere recorded. In 1892 it was 29,826. In 1902, the last year for which reports are published, the births were 29,841. In 10 years, according to these ridiculous and misleading figures, the births in a year in this city had grown only 15. The population had grown some 450,000. The number of married women in this city in 1890 was 188,326. The number of married women in 1900 was 238,258. Here is an increase in the decade of 49,932 women living in marriage. Yet births had grown only 15 from 1892 to 1902, and in 1900 the registration division of the city Health Bureau reported only 29,105 births, against 29,764 births in 1890. The population in these 10 years had grown from census year to census year 446,527, and the married women 49,932, as already shown, but the registration division of this city could only find 659 less births in 1900 than in 1890. This disparity has but one explanation—the births are not registered. For a dozen years their number has been stationary. Down to about 1890 the number grew with population. In 1882 the births were 21,237. They increased normally, though undoubtedly deficient, for all the years until the city came to pass a population of 700,000 or 800,000. The vast human jungle grew big enough for concealment. From 100 to 200 births a week pass without registry.

SOUTHERN STATES.

Gulf Boards of Health to Combat Yellow Fever.—A Gulf States conference, composed of the Presidents of the Boards of Health of the Gulf States, will probably be the outcome of the recent tour of inspection of Mexico by the Presidents of the Boards of Health of Mississippi, Alabama, Louisiana, and Texas. Dr. Arthur Nolte of the Louisiana board said that this is what would probably be done, though it had not been definitely settled.

For Hospital at Hagerstown, Md.—It is reported that 4 bills have been drafted to be introduced in the Legislature providing for the granting of a charter to the Washington County Hospital Association for an annual appropriation from the State of \$6,000, and to enable the County commissioners and mayor and council of Hagerstown to levy annually for certain sums for the support of a hospital to be constructed. The affairs of the hospital are to be conducted by a board of not more than 11 trustees, to serve without pay.

WESTERN STATES.

Trained Nurses Desire a Protecting Law.—According to the Illinois State Association of Graduate Nurses, amateur nurses, dressed in the costume of the graduates, are imposing on persons who require such services. The State organization is working for the enactment of a statute that will provide for the registration and examination of all graduate nurses. Sister Ignatius Penny of the Mercy Hospital, the recording secretary of the association, said recently that last year the registration bill was passed, but at the last moment was vetoed by the Governor.

Smallpox among the Indians of the Northwest.—Information from Manitoba, under date of March 2, says: A terrible scourge of smallpox has nearly wiped out the Indians of the Isle of Lacrosse district, 60 victims being numbered within 2 days. The epidemic, according to the latest reports, has extended to Portage LaRoché, and the natives, fleeing from the danger, are spreading the disease. The Roman Catholic mission at Lacrosse, under Father Simeonin, is making heroic efforts to cope with the situation. An expedition provided with medical comforts and escorted by a body of Northwest mounted police, has been dispatched to the scene.

Medical Legislation in Colorado.—Some months since, intelligent physicians of Colorado, regardless of the school to which each belonged, recognizing the need of medical legislation, selected committees representing the regular, eclectic, and homeopathic schools, and these conferred as to the best means of securing the much needed legislation. In *Colorado Medicine* for February, appears a report from Dr. S. D. Van Meter, chairman of the combined committees, with certain recommendations. It is in part as follows: After careful study of the existing Colorado Medical statute, and due consideration of the several futile attempts made in the past to replace it by something better, we, as a joint committee composed of the chairmen of the Legislative Committees from the Colorado State Medical Society, the Colorado Homeopathic Society, and the Colorado State Eclectic Medical Association, have concluded that amending the defective parts of the present law, is the most expedient, the most practical, and the most probable attainable legislation. We, as a joint committee sustained by each and every member of the 3 committees, have harmoniously agreed upon the necessary amendments, an epitome of which is as follows: 1. The repeal of the "Ten Year" clause. 2. The adoption of an amendment increasing the fee for registration on diploma to \$10, and by examination to \$25, and further, provid-

ing for the maintenance of the State Board of Medical Examiners from fees received, instead of by appropriation. 3. The adoption of a clear, broad, legal definition of what constitutes the practice of medicine. 4. The adoption of an amendment empowering the State Board of Medical Examiners to refuse and revoke licenses for immoral, dishonorable, or unprofessional conduct.

FOREIGN NEWS AND NOTES

GENERAL.

Women Live Longer Than Men.—A foreign exchange says: Women live longer than men. Taking female lives at any age you choose, it is seen from complete and authoritative tables that a woman may always look forward to a longer life than a man of her own age. Accidents will occur to upset the truth in individual cases, but as a whole the fact remains. Although in the British Isles more boys than girls are born, baby boys die in so great a proportion that girls are presently in a majority. On the day of his birth a boy has a natural right to expect a life of 41 years, 4 months and 1 week, whereas a girl, according to experience, is likely to live for 44 years, 7 months and a fortnight. Those of either sex who reach the age of 5 have a still greater prospect of living long and usefully than they had before they were 1 year old. Up to that point of time they may be said to be growing younger, in the statistical sense, instead of older; because each year brings them the promise of others in excess of years past. But at the age of 6 their expectation begins to diminish year by year. At 21 the boy is doomed by average to die 38 years and 8 months later, and the girl at a few days short of age 62. The softer sex retains its advantage all the way, and even centenarian women may look forward to living a day or two longer than if they had been centenarian men. Moreover, the women aged 100 will be more than twice, and nearly thrice, the number of equally aged men.

Unsanitary Conditions at Panama and Colon.—Recent information states that Surgeon J. C. Perry, of the Public Health and Marine-Hospital Service, who has been at Colon making a special study of the sanitary conditions on the Isthmus, has submitted an exhaustive preliminary report to Surgeon-General Wyman. He describes the present condition of Colon as unsanitary and unhealthy, and says that its redemption will be an immense task. The climate at the camps along the route of the canal he describes as far superior to that of Colon and Panama, and he says that with proper sanitary regulations the health of their occupants should remain good. "The most common and fatal disease in Colon is malarial fever," says the report, "especially the pernicious forms. This disease exists throughout the year, but is more prevalent and severe during the rainy season. All types of malarial fever are more frequent in Colon than Panama, and the pernicious forms more prevalent. The question now naturally arises: Can Colon be made a healthy town? I think this can be answered in the affirmative; that is, a healthy tropical city. Briefly mentioned, it means filling in the entire island on which the town is built, the installation of a good supply of water and sewerage system, the destruction of the greater number of the buildings now occupied by the negro population and the construction of new houses on sanitary principles and the enforcement of sanitary regulations."

Changed Views on Suicide.—Bentham, writing in the earlier half of the nineteenth century, complained that juries were constantly guilty of perjury when they declared a suicide to have been *non compos* at the time of his decease. The recent verdict upon Whitaker Wright would have seemed to the great jurist to mark a return to ancient candor, however much the announcement that a man had a motive for suicide and died in his senses may startle people today. The verdict of the jury and the coroner's remarks at the inquest on the body of Whitaker Wright should, indeed, serve as a reminder that the law does not necessarily regard suicide as the result of insanity, and that even where it seems to admit insanity, it isolates it in a manner quite contrary to scientific ideas of causation. In cases, for instance, where suicide has closely followed the making of a will, the law has repeatedly refused to invalidate the testament because the testator took his own life shortly after writing it. The notion that a man is out of his senses when he commits suicide really dates from the day when the Church insisted that suicides, as persons guilty of self-murder, should be buried with the utmost ignominy. Lay jurymen in those days, to save their fellow creatures' bodies from disgrace, preferred to suppose that a suicide was insane at the time of death, and therefore irresponsible. The plea of insanity in early times was frankly put forward as a legal fiction, actuated by kindness, and as such was probably freely accepted by individual priests. It is difficult to say exactly when what now seems to be a firmly rooted belief began to prevail that a suicide is out of his senses at the time he puts an end to himself. In the eighteenth century a connection between abnormal mental conditions and suicide appears gradually to have arisen, and in 1788 "self-destruction" and "phrenzy" occur in the same book title as though the one connoted the other.—*The Lancet*.

OBITUARIES.

Franklin Staples, at his home in Winona, Minn., February 22, aged 70; a graduate of the College of Physicians and Surgeons, New York, in 1862; a charter member of the Minnesota State Medical Society, and one time its president. A member of the American Medical Association and vice-president of the Association in 1877. In 1874 he became a member of the State Board of Health of Minnesota and in 1899 was elected its president, in which office he continued to the time of his death. In 1883 he was elected professor of medicine in the medical department of the University of Minnesota, which position he held for some years. He was widely and favorably known in the Northwest.

Ogden Curtis Ludlow, at his home in New York, March 2, from typhoid fever. He was born on Staten Island, and was a graduate from the New York University and the College of the City of New York. He was a member of his County Medical Society, the State Medical Association of New York, and the American Medical Association. He was a member of the Alumni Association of St. Luke's Hospital, and was attending physician to St. Joseph Hospital. He was a Founder of *American Medicine*.

James Madison Laird, at his home in Fayette county, W. Va., February 16, aged 51; a graduate from the University of the City of New York. According to a correspondent, who writes touchingly of the life and character of Dr. Laird, he was truly a doctor of the "Old School," practised widely in the country districts, gave much to charity and was correspondingly loved and revered.

Theodore Yound Kinne, at his home in Paterson, N. J., March 4, of heart disease, aged 64; a graduate of Albany Medical College in 1862. During the latter year he was appointed assistant surgeon of the New York Volunteers. He was twice president of the Paterson Board of Health and widely known in that vicinity.

Howard C. Russell, at the Marine Hospital at Stapleton, Staten Island, March 2; a graduate of the University of Pennsylvania. He was appointed to the Marine-Hospital Service July 1, 1897, and served at different hospitals in the South and on the lake coasts until 1902, when he was transferred to Staten Island.

William Alfred McCorm, at his home in Long Island City, N. Y., February 18; a graduate of the University of Buffalo in 1882. He was formerly superintendent of the Elizabeth, New Jersey, General Hospital.

Clinton Toy, at his home in Mineral, Texas, February 24, aged 38; a graduate of the Memphis Medical College in 1897. For a young man Dr. Toy was widely and favorably known in the community in which he lived.

John M. Minnich, at his home in Wichita, Kan., February 22, aged 62; a graduate of the Cincinnati College of Medicine and Surgery in 1877. A member of the Kansas State Board of Health for a number of years.

Henry Rosenstock, at his home in Philadelphia, February 23, from Bright's disease; a graduate of Jefferson Medical College, Philadelphia, in 1896. He had recently practised in Scranton, Pa.

Adolph Opperman, at his home in Cordell, Okla., February 18, aged 61; a graduate from a German medical school in 1881, and a well-known practitioner in the vicinity in which he lived.

John Dickinson, at his home in Cleveland, Ohio, February 19, aged 70; a graduate of Cleveland Medical College in 1867. He was an army surgeon during the Civil war.

William G. Taylor, at his home in Columbia, Lancaster county, Pa., March 4, aged 58; a graduate of Hahnemann Medical College, Philadelphia, in 1870.

Peterson Bryson Wood, at his home in Baltimore, February 19, aged 44; a graduate of the Columbian University, Washington, D. C., in 1883.

Moses D. Knight, at his home in Clinton, N. J., March 7, of heart disease, aged 71; a graduate of the University of Pennsylvania in 1861.

Thomas Nicholson Drake, at his home in Wilson, N. C., February 13, aged 74; a graduate of the University of Pennsylvania in 1856.

True M. Gould, at his home in Raymond, N. H., February 15, aged 72; a graduate of the Dartmouth Medical College in 1855.

A. L. Pattison, at his home in Plattsburg, N. Y., March 3, aged 76. He was widely and favorably known in northern New York.

E. Graves Kittson, at his home in Hamilton, Ontario, February 4, aged 52; a graduate of McGill University, Montreal, in 1873.

Andre L. Cowles, at his home in Spartansburg, Pa., February 18, aged 60; a graduate of the University of Buffalo in 1892.

Albert A. Hanna, at his home in Baltimore, February 5; a graduate of the University of Maryland, Baltimore, in 1875.

Charles P. Pillsbury, at his home in Duluth, Minn., March 2; a graduate of Hahnemann Medical College, Chicago.

Whipple W. Clark, at his home in Old Fort, N. C., February 15; a graduate of Jefferson Medical College in 1882.

CLINICAL NOTES AND CORRESPONDENCE

[Communications are invited for this Department. The Editor is not responsible for the views advanced by any contributor.]

EXTRAUTERINE PREGNANCY: AN INTERSTITIAL CASE: RUPTURE BY EXAMINATION.

BY

W. L. WALLACE, M.D.,

of Syracuse, N. Y.

Mrs. D., aged 24. I first saw the patient January 5, 1904.

History.—She has one child 3 years old and one 13 months, which nursed until 7 months old, August, 1903, when the mother's breasts dried up. The patient menstruated regularly from the second month, the last time October 30, when the baby was 10 months old; no blood or other discharge since. December 1 she passed over her menstrual time, had much nausea, and thought herself pregnant; she had occasional pains after December 1, and on Christmas day had quite hard pain for a short time, but no tenderness. On December 28, at 5 p.m., there was sudden severe pain located around the navel; this lasted all night, no faintness, patient screamed. A doctor was called, but could find nothing, and concluded that an abortion was threatened. Patient was confined to bed a week by pain and tenderness, but gradually improved. No chill and no bladder or bowel symptoms.

January 5, the patient had been up around the house 2 or 3 days. At 3 a.m. she was awakened by severe pain, which lasted an hour, and was again severe at 7 a.m., and continued so all day.

Her physician saw her during the forenoon, and found general abdominal pain and tenderness; no distention. Temperature, 99°; pulse 80.

At 5 p.m. her physician found great pain, tenderness, and considerable distention. The bowels had moved the previous day. Patient had had much nausea and vomiting all day. Temperature, 99.2°; pulse, 100.

Examination.—I saw the patient at 8 p.m., January 5, 1904, in consultation with Dr. Chaffee.

Her pallor was striking, so that the first thought was hemorrhage from extrauterine pregnancy; however, any prejudice in this direction was dispelled by finding the pulse 80, temperature 98.2°. The abdomen was not distended, and not very tender. A watery discharge was squeezed from the nipples. There was no vaginal discharge.

The uterus was very low, culdesac bulging and very tender. I could feel no mass, and the extreme tenderness fortunately prevented any satisfactory examination.

Diagnosis.—Probable extrauterine pregnancy, in spite of the fact that there had been no irregular bloody vaginal discharge. The patient was sent at once to the Good Shepherd Hospital, in an ambulance, at 9 p.m., for further observation.

January 6, temperature 99° to 100°, pulse 80 to 90. Leukocyte count 10,400. Considerable pain and much tenderness.

January 7, no improvement in the patient's condition, and she was therefore taken to the operating-room at 9.15 a.m. for examination under ether. The uterus was found to be enlarged to the size of a 4 to 6 weeks' pregnancy; no mass could be felt at the side or posteriorly. The uterus was retroverted and at the left.

I replaced the uterus easily, and not finding a mass concluded that we were dealing with an incarcerated pregnant uterus and threatened abortion.

At 9.30 a.m., the patient left the operating-room, pulse 120. At 9.45 a.m., I was called. Pulse was 180, patient perfectly conscious. I watched the patient for 5 minutes while the operating-room was being prepared. The pulse dropped to 140 and therefore I waited 5 minutes longer for preparation of instruments. The pulse became poorer and poorer, but somewhat slower; there was great pallor and air hunger.

At 10 a.m., as the patient was being placed on the table, apparently dead, I punctured the culdesac, as I could not believe that the pulse could keep getting slower with a fatal hemorrhage. Fresh blood gushed from the puncture.

I now rapidly opened the abdomen, without stopping for an anesthetic. Patient was unconscious, and gave no sign of life. The abdomen was full of bright red blood. The hemorrhage was stopped, the abdomen washed out with hot saline solution and while the abdomen was being closed intravenous saline solution was administered. As soon as the hemorrhage was stopped and the hot saline solution started, the pulse returned, and the patient commenced to show signs of pain. A few whiffs of chloroform were then given. Half an hour later the pulse was 140 and it soon fell to 128.

The temperature and pulse stayed high for 3 days, and the patient had headache. The wound healed by first intention, and by the end of a week the patient was in excellent condition.

Now, to return to the conditions found at the operation. There were no adhesions, and no clots were present.

I reached in and pulled up the right tube and ovary. They were normal, and were dropped back. I then reached the left tube and ovary, and was surprised, as they also were normal.

Dropping the left tube and ovary, I reached the uterus and pulled it up into the incision. It was enlarged, as if about 6 weeks pregnant. A ragged rent was found in the right cornu of the uterus, large enough to hold a horse-chestnut. Chorionic villi could be seen in this cavity. The tube itself looked perfectly normal, and was entirely separated from the uterus. An artery coming up at the side of the uterus was pumping a large stream with great force. This artery was tied, and the opening in the uterus was closed, after the ragged edges had been cut out, by an incision which extended down to the uterine mucosa, including an oval 2 in. by 1 in., and nearly 1 in. deep. The fetus was found floating in the blood. It was about 1½ inches long. The uterus was larger than in any other extrauterine case I have seen, and may contain another fetus. This would account for the unusual fact that there was no external hemorrhage before or after the operation.

BOARDS OF HEALTH.¹

BY

G. W. WAGONER, M.D.,

of Johnstown, Pa.

The conservation of the public health is the highest function of municipal government. Trained and educated men are required to pass judgment upon questions bearing upon health. Taken in the rough, a Board of Health might consider its duty performed when it issues edicts concerning the disposal of garbage and the cleaning of back yards, alleys, and waste places. If it compelled the enforcement of its laws relating to filth and looked about upon a tidy city it might feel it was a model board. Yet the mortality of the city might not have been reduced nor infectious diseases prevented.

Board of Health operations are frequently not of the positive value to the public that the extreme importance of the matter demands. And perhaps it will always be so until public opinion and health laws permit an official to enter into the sacred privacy of a home and the still more sacred privileges of a man's habits, in the absence of a distinctively infectious disease, to investigate, condemn, and compel the observance of sanitary laws. Within these individual preserves the seeds of all infectious diseases find the richest soil for development. Until suspected disease can be brought under the law effectively, the people educated to a belief in the necessity of its discovery; and the laws then executed by trained officials, there can be no ideal Board of Health.

Open and exposed filth is offensive to good taste, and indirectly prejudicial to good health, but in the presence of the sun and the air, the great disinfectors and destroyers, it is disarmed of much of its power for harm. It is the secret household, and personal filths which are the factors in disease and these cannot be reached except by education, advanced legislation, rigid enforcement, and trained men of brains to execute the laws.

A Board of Health should be composed of scientific men, or the majority should be such, and the remainder men of broad views, good practical sense and able to see the far-reaching effects of scientific methods of prevention and sanitation. When I say scientific men I mean men of liberal education and special training in all the branches of science which have grown into prominence since the germ theory of disease has been established. Such a board should have no connection directly or indirectly with politics. The terms of office should be long; the object being to make it as nearly permanent as possible. For the needs of each locality would require study and treatment. The health officer, or the executive officer of the board, should be a physician, who, to his medical education, has added special training in hygiene in its broadest sense. He should be paid a sufficient salary to justify him in devoting his entire time to the duties of his office. He should have assistants to attend to the gross duties of the board while his attention is directed to the more serious questions of the discovery of dangerous conditions which might surround localities, houses, or individuals; the prevention of diseases; the collection and classification of statistics, and the preparation of instructions, both to individuals and the general public, how to

prevent diseases and manage the hereditary defects of individuals.

The management of external filth and gross nuisances are merely a question of executive detail. The laws now in force are sufficient to cover almost every case of ordinary nuisance. The powers to isolate and quarantine infectious diseases are ample for a courageous board and health officer, but not distinct enough for weak-kneed officials. The ideal health officer, with a comprehensive knowledge of health regulation can meet all these questions with certainty. But some of the questions, which, in their examination and settlement, encroach upon the personal rights of the individual have not yet been settled by any general law. Take pulmonary tuberculosis for example. This great "White Plague" must be considered an infectious disease. The victim is a source of danger to the public from almost the inception of the disease until its termination in death. What shall be done by a Board of Health to protect the public from danger? Shall the diseased ones be isolated? If so, many of the individuals in civilized communities must be rigorously excluded from society. They must not be allowed to transmit their fatal taint. The healthy ones must be charged with their maintenance. Such an undertaking carried out to its last detail would be impracticable, and beyond the power to enforce of any government based upon the popular will.

Syphilis is another disease the poison of which is disseminated by the unlawful gratification of the irresistible instinct which peoples the earth. This poison vitiates the fountain of life at its source and fastens a curse upon generation after generation. The propositions to control or limit in the slightest degree the spread of this taint are received with horror and contempt by almost all classes of citizens, and yet there is no household so pure that it may not enter therein, no person so saintly that the poison may not be instilled into his veins. The fatal temptation is presented to all, but successful resistance does not protect. The unclean are everywhere and victims are made by the proper association of individuals. Here, too, the ideal Board of Health should stand as an insurmountable barrier to the propagation of this disease, but he is a dream indeed, who thinks for an instant that any power could prevent all the calamities incident to the passions which have for the object the preservation of the species.

In the matter of fighting smallpox and attempting to stamp it out of a community it may be stated as a fact which cannot be controverted: When the methods used by a Board of Health are not in strict accordance with scientific truth, proved and demonstrated in countless investigations and experiments, such methods are deceptive, useless, expensive, creating a false sense of security and are discreditable to the community.

What are the doctrines of science in relation to smallpox? It is unquestionably the chief one of all the infectious diseases. The characteristics of infectious diseases are more highly accentuated in it than in any other. It is intensely infectious. The morbid germ enters the organism from without. This means something more than contagion, when one comes in more or less close contact with a person sick with the infectious disease, and contracts the disease by reason of that contact. It may be that many people think they cannot "take" smallpox unless they come in contact with a smallpox patient. This is one of those mistakes of belief which are almost crimes. The germs of smallpox may, by ignorance and stupidity, be scattered far and wide, and by reason of their persistent vitality be a source of danger for years. They are clinging to any substance. They are volatile and may be wafted through the air for definite distances. It is the failure to recognize these vital points that causes the mysterious development of so many cases of smallpox. The fact of the intensely infectious character of the disease is the central one upon which successful efforts at prevention and suppression must be founded.

The first law is, therefore, evolved: "The poison germ of smallpox must not be removed to another place." Another fact that history has made painfully evident, is that the human race when unprotected is certainly susceptible to smallpox. The exceptions are so few and uncertain that they need not

¹ Read before the Cambria County Medical Society, December, 1908.

considered. In 1766, Dr. Brooke, an old-time medical authority of England, wrote: "Smallpox has been for ages, and continues to be, the terror and destroyer of a great part of mankind. In the ordinary course and duration of human life scarce one in a thousand escapes the smallpox." But science has demonstrated to the satisfaction of normal minds that by the practice of proper vaccination the susceptibility of any individual to smallpox may be positively destroyed.

It is not my purpose to argue the question of vaccination. I am striving only to state facts. The second law is, therefore, laid down by science.

"By vaccination and revaccination the predisposition to smallpox in the human race may be again and again destroyed."

Upon the recognition and enforcement of these 2 laws depends the control of this most loathsome and dangerous disease.

Isolation of those having the disease and also of those suspected of having it is the first step in the fulfilment of the first law.

Isolation that is complete, certain and continuous for both classes.

Isolation cannot be complete, certain and continuous in the houses of smallpox patients. There are so many opportunities—so many chances to break through the imaginary wall of isolation, that the inmates of the house will violate the law. All means so far tried of isolating patients in their homes have been failures. If the Board of Health undertaking the supervision of the isolation is perfunctory in its methods the attempt is ridiculous, costly, and often beneath the contempt of scientific men.

Isolation should be carried out in a properly constructed municipal hospital having accommodations for all classes of people, and under scientific control. To such a hospital all cases, without exception, should be taken. The safety of the community is of more importance than the personal pride or feelings of any individual. All patients should remain until absolutely free from poison germs and until repeatedly disinfecting, whether that time be 1, 2, or 3 months.

The suspected cases should also be taken to a department of the hospital away from the danger of smallpox, where they can be safely kept, observed and treated until the nature of the case is determined, when they may be released or transferred to the smallpox wards if necessary.

If these 2 classes of patients were promptly removed from their home surroundings, and those remaining in the house were immediately vaccinated and revaccinated, a quarantine under guard established for a period of safety, and the house then thoroughly cleaned and disinfected, the foci of infection would be speedily destroyed. As to disinfection it should be understood that the simple evolution of an indefinite quantity of formaldehyd gas and the closure of the room for a few hours is a delusion and a farce. Such disinfection destroys nothing—purifies nothing. When we read of the disinfection of a room one evening and its occupancy the next morning, we laugh at the silly blunders made in the name of science.

Cleansing and disinfecting a room or a house is a serious matter, and should not be left to the immature judgment of a novice.

I do not propose to describe the proper technic of disinfecting rooms and houses further than to say the vapors of chlorin, sulfur or formalin must be retained in the apartments for at least 24 hours; after fumigation the rooms should be exposed to the air and sunlight for 3 or 4 days. The wall paper should be removed and replaced, or the walls and ceilings rubbed off, and then painted or papered; the floor, woodwork, and furniture washed down with hot carbolic acid solution. All the debris from the rooms burned, and all closets, chests, and dark corners opened up, cleaned out, disinfected, and aired. All this means intelligent work, but by such work the community is protected.

In fulfilment of the second law vaccination and revaccination should be compulsory in the most comprehensive meaning of the term.

In the light of these principles I ask, Are we safeguarding the public against smallpox? I answer, No. I say this in dis-

tinctive condemnation of no one or of no methods used; for those striving to control the situation are evidently working up to the limits of their resources. If condemnation is due any one, it justly falls upon the scientific physicians of any city, who, knowing these facts, have failed to proclaim them to the people and thereby develop such a public sentiment as would compel the adoption of scientific methods in the management of the filthy disease. I appeal to you all, that you do proclaim and defend the truths of your science until money and power are forthcoming for the preservation of the public health. With these essentials gained the execution of scientific sanitary methods will immediately follow, and the disgraceful disease be driven from us.

If the government is to regulate the public health and suppress disease, the examples cited will indicate what an enormous job it has undertaken. They also indicate that the power of a Board of Health should only be limited by the laws of science and the intelligent discretion of the board in matters of public health and hygiene.

For a Board of Health to be efficient, practical, and able to accomplish the work for which it is organized it should not depend upon the direct cooperation of any one. I mean that it should be so well organized, have such resources at its command, and employes at its disposal, that all the work could be done by its own people.

The practice of depending upon physicians to report all infectious diseases and other matters coming under the authority of the board, is not a good one, for the reason that the results are very imperfect. While physicians may appreciate the necessity of making such reports there are many reasons operating to cause them to neglect the duty. As a consequence, a small proportion of the milder type of infectious diseases is not reported, and such cases are most dangerous to the public. The duty of reporting cases should not be imposed upon medical men alone. The information is wanted for the public, and the public should provide means to get it at its own expense. I think the health officer should be charged with the duty of getting all the facts concerning each case of infectious disease, and not the physician. All that should be required of the physician should be a statement that, in a particular house there is a case of infectious disease, giving the diagnosis, then the health officer should ascertain the facts and attend to all details that concern the public interests. He should be required to visit each physician at short intervals to receive reports and other proper information. By such a plan the responsibility and authority would be concentrated in the Board of Health where they belong, and the physician freed from an annoyance which he should not be compelled to endure.

A board working upon such a basis and with all the duties and authority concentrated in it instead of being diffused over an indefinite number of persons could control epidemics and gather material for statistics and conclusions which would be valuable. Under the present system such statistics are without value and cannot be taken as the final factors in determining the origin, development, and progress of a disease.

This plan may be elaborated to meet all the conditions under which a modern Board of Health could act, and I believe it would increase its usefulness. It would entail an increased cost for maintenance, but the results shown in public health, cleanliness, decency, and the stamping out of infectious diseases would justify the increased expenditure of money and the conferring of unlimited power, within well-defined limits, upon a scientific Board of Health.

Paraphrasing the old motto, I present the following as the rule of action for Boards of Health:

"Eternal inspection is the price of Public Health!"

A NOTE ON CEREBROSPINAL SYMPTOMS IN INFECTIOUS DISEASES APROPOS OF A CASE OF TYPHOID FEVER.¹

BY

ALFRED GORDON, M.D.,

of Philadelphia.

Instructor in Nervous Diseases, Jefferson Medical College; Assistant Visiting Neurologist to Philadelphia Hospital; Neurologist to Douglass Memorial Hospital.

During a very long time there was a belief that each organ lived separately from the rest of the body and that the suffering of one organ had no influence on others. An entirely different view is held now; there is a unity and solidarity among various parts of the living organisms; when one organ is affected, the entire system suffers. A bacillus, typhoid for example, produces a local focus of infection in the intestines, but the toxins circulating in the vascular system will have an influence on the whole economy by means of their chemic combinations with Ehrlich's lateral chains of the cells. The characteristic feature of toxic agents is that each has a special affinity for certain protoplasmic molecules and cells of certain organs. An infectious agent will attack by preference a certain organ primarily, but the poisons secreted by it will show their secondary effect throughout the entire system.

The nervous system, generally speaking, presents a feeble organic resistance to toxic products. It is, therefore, very frequently affected in infectious diseases, but the character of the involvement of the nervous system is not always the same. While in some cases the infectious agent or its toxins produce profound and unalterable changes, in others its effect shows itself only in *transient* circulatory changes. The latter may, however, be sufficiently pronounced to present clinical phenomena indicating disturbed functions of certain centers. Owing to the fact that the changes of the nervous system are dependent upon the localization of the infectious element, it is readily understood that all possible forms of cerebral or spinal diseases are met. There are, however, certain forms which are frequent, and others that are very rare. General symptoms pointing to an involvement of the meninges of the brain are of frequent occurrence. Delirium, stupor, and general prostration also belong to the frequent complications. The peripheral neuron in whole, or in part, suffers not infrequently in infectious diseases; anterior poliomyelitis, transverse myelitis, and multiple neuritis are the forms we meet now and then. Hemiplegia, however, occurs mostly in childhood, more rarely in adults. Symptoms pointing to an involvement of cerebral ganglions or of special centers of the brain are not frequent. Such cases have been reported, but they are comparatively few.

It is difficult to find the proper reason for the fact that while symptoms of organic diseases of the brain are rare, symptoms of involvement of the meninges are frequent. A still greater difficulty one finds when an explanation is sought to determine the cause of *transient* forms of organic diseases of the cerebrospinal system. That an infectious agent or its products are liable to injure permanently a certain portion of the cerebrospinal system and produce secondary degenerative processes is a matter easily conceived; but the disappearance of a genuine hemiplegia or other paralysis without any consequences is certainly unusual and difficult to explain. However, the conception of a localized meningitis is sufficient most of the time to explain the nervous phenomena observed in infectious diseases. The absence, postmortem, of inflammatory processes in centers of the nervous system in those cases which presented *ad vitam*, *transient* symptoms of nervous diseases, does not exclude the possibility of a localized meningitis in a great many cases. The existence of serous meningitis and of curable meningitis is proved beyond doubt.

The most recent investigations of the nature and of the chemic composition of the cerebrospinal fluid in meningitis are of very great importance for diagnostic purposes. The studies of this fluid, and especially its cytology, have shown

conclusively that between the very favorable cases and the fatal ones there are various degrees of meningitis. This circumstance gives us a key to understand why in some cases the nervous phenomena are multiple and at the same time transitory in character.

The case I am about to report offers a peculiarity from the latter standpoint. The symptoms were multiple, and pointed to a grave involvement of both the brain and the spinal cord. The association of the symptoms was quite unusual, as in the literature at my disposal I could not find a similar case. Finally, the peculiarity of the case lies in the transitory character of the apparently grave symptoms.

The history of the case is as follows:

G. W., colored, aged 17, was admitted to the Douglass Memorial Hospital, November 17, 1902. The data regarding the onset of his illness before his admission, the examination on admission and the subsequent course of the disease corroborated by a positive Widal test, proved that he was suffering from a typical, but uncomplicated case of typhoid fever. On the day of his admission his temperature was 102° F. A few days before he was brought to the hospital, the relatives said that he lost suddenly his speech and was unable to stand and walk. The patient came under my observation 10 days after admission, and these are the symptoms I found: Total motor aphasia, agraphia, and word-blindness, but no aphonia; right hemiplegia, including the face, but the motor paralysis was not much pronounced; slight hyperesthesia of all forms of sensations on the same side; rigidity in both lower extremities with ankle-clonus, greatly exaggerated patellar tendon-reflexes and Babinski sign on both sides. The patient was unable to stand unsupported or to walk. There was also incontinence of urine and feces. The total absence of hysteric stigmata and the previous history of the patient made me reject the possibility of a functional nervous disturbance.

At the time the examination was made the patient entered into convalescence of his original disease. In view of the multiplicity of the symptoms out of proportion with the patient's general condition, I made a favorable prognosis. The patient gradually improved and made an uneventful recovery. He left the hospital in perfect health.

The case appeared to me to be of sufficient interest to warrant me reporting it. The great number of symptoms pointing to grave cerebral and spinal lesions developed in the course of typhoid fever, and having disappeared with the recovery from the latter disease, appear to me to be very instructive for the following reasons:

1. An apparently mild case of typhoid fever without any complication in other viscera may affect the whole cerebrospinal system simultaneously.
2. The nervous symptoms may be very much pronounced and multiple in spite of the mildness of the original disease.
3. These multiple and marked organic nervous symptoms may be out of proportion with the general conditions of the patient, as generally speaking, we know that the more the infectious disease is pronounced in its course, the more profound is the toxemia and the more symptoms of complications may be expected.
4. The prognosis is usually favorable in cases in which this *disproportion* is present, as these apparently alarming symptoms are only transitory in character.

The case is also unusual from this point of view, that if aphasia and hemiplegia in the course of typhoid fever were rarely observed, agraphia and word-blindness to my knowledge were not reported.

Contract Surgeons in the U. S. Army to be Abolished.—A bill which has been recently introduced in Congress, and which will probably become a law, provides that in place of the body of contract surgeons, a "medical reserve corps" shall be created. The President is authorized to issue commissions as first lieutenants in this corps to graduates of reputable schools of medicine, who are properly qualified. Contract surgeons now in the military service, if recommended by the surgeon-general, are eligible without further examination. The holder of a commission in the medical reserve corps is to have the authority, rights and privileges of a commissioned officer of the same grade in the regular medical corps, except as regards promotions, during the time he is actually called into active duty. The pay and allowances of first lieutenants of the medical corps shall be given to them for the same period. The system is made flexible by a clause providing that no officer of the medical reserve corps shall be ordered into active duty, if he is unwilling to accept such service, and by another clause which permits such officers to serve with the militia or volunteers, or in any other capacity under the national Government.

THE MODERN PHARMACOLOGY OF IRON.¹

BY

REYNOLD WEBB WILCOX, M.D., LL.D.,

of New York City.

Professor of Medicine at the New York Postgraduate Medical School and Hospital; Physician to St. Mark's Hospital.

The modern pharmacology of iron dates from the time when the questions of source, form, absorption and disposal were studied under the auspices of scientific methods of research. Since this metal is essential to the life of many, and probably of all, forms of protoplasm, the question is important. To be sure, in the vertebrates, most of the iron is contained in the hemoglobin of the blood, yet it is by no means confined to the red blood cells, for in 1886 St. Szcz. Zaleski discovered iron-bearing bodies in the tissues of the body. This statement was confirmed by Woltering and Spitzer, who showed the existence of these bodies in the testicles and spleen. Later, iron-bearing bodies were isolated by Schmiedeberg from the liver, and by Bunge from the yolk of an egg. To Dartre and Floresco belong the credit of showing that the iron in the food and the iron in the tissues were interchangeable. Inasmuch as under ordinary circumstances the growing vertebrate obtains sufficient iron from his food for the rapid increase in the bulk of his blood and the proportionate augmentation of his hemoglobin, this result was *a priori* the expected one. In great measure, confirmatory of this was the observation of Leichtenstern that iron-bearing food caused an increase of iron in both the blood and the tissues of the human being. About the time of Zaleski's report, Naunyn and Minkowski showed that iron is retained in the liver in the form of iron-bearing pigments and proteids. The practical contributions to iron therapy were based on the statement of Hammarsten, that the addition of iron to the food exercised a great influence upon the number of red blood cells and their hemoglobin content, and the studies of Quincke and Hochhaus, who showed the exact course of iron after its absorption from the duodenum. Practically all authoritative opinion is voiced by Schmiedeberg, who states that iron as it exists in the food is undoubtedly the blood-forming combination.

The next step was to determine in what form iron exists in the food. Practical investigations demonstrate that inorganic iron when it comes into contact with the hydrochloric acid of the gastric juice is converted into iron chlorid, which, by coagulating the superficial layer of the gastric mucous membranes, produces dyspeptic symptoms. Such conditions experimentally produced show on microscopic examination a congestion and swelling of the mucous membrane with its surface covered by a coagulum composed of necrosed cells and inflammatory exudate. Among the reasons for the avoidance of inorganic iron to supply the iron for the hemoglobin of the red blood cells, it is not necessary to include Bunge's now long-ago exploded hypothesis. Schmiedeberg presents the consensus of opinion of workers in experimental therapeutics when he states that inorganic iron is not only inadequately absorbed to meet the demands of the body for iron in disease, but that the disturbances of digestion resulting from irritation to the gastric mucous membrane from prolonged use counterindicate it.

Evidently, modern iron therapy is based on the administration of an iron compound which shall be chemically identical with that existing in the food, namely, an organic iron. Here the term "organic" is used in a special significance. It does not refer to the combination to which the iron is attached, but rather to

the method of attachment. For instance, iron acetate must be considered an inorganic iron because it can be dissociated and the iron precipitated by ammonium sulfid. In the modern use of the term as applied to iron, "organic" should be considered obsolete and "masked" substituted.

At first sight hemoglobin, when administered by the mouth, would seem to be a proper organic iron for exhibition in anemia and allied conditions. As a matter of fact, Cloetta as early as 1896 showed that it is not absorbed as such, but is destroyed so soon as it enters the stomach. With this the theory of the advantage of blood, or products made from blood, for oral administration, falls. The crucial test for the actual organic or masked iron preparation, is that advanced by MacCallum. Briefly, a small quantity of $\frac{1}{2}$ of 1% solution of hematoxylin is added to the iron compound to be tested. If the iron is inorganic, a characteristic blue-black color is produced; if the iron is organic or masked, no color reaction results. That many so-called organic iron compounds are practically only combinations of iron salts with albuminoids is readily demonstrated by the addition to them of a few drops of a silver nitrate solution, which will cause a precipitation of these albuminoids. Gottlieb claims for organic iron that it is not astringent, does not disturb digestion, is more easily assimilated, and is in the complex form required by the blood and tissues. In determining the form of masked or organic iron for oral administration, one should be selected which (1) should be of definite chemie composition; (2) does not precipitate with a silver nitrate solution; (3) does not give the blue-black color with MacCallum's test; (4) is not decomposed by the hydrochloric acid of the gastric juice; and (5) it must show definite results in (a) an increase in the number of red blood-corpuscles and (b) in the amount of contained hemoglobin. These requirements are evidently the most rigorous which can be devised, and in meeting them modern iron therapy will be placed upon a secure foundation.

ALOPECIA AREATA.¹

BY

FREDERICK H. DILLINGHAM, A.M., M.D.,

of New York City.

Adjunct Professor of Dermatology, New York Polyclinic; late Assistant Sanitary Superintendent, Department of Health, City of New York.

The term alopecia areata should only be used to designate a disease, in which the hair falls out in one or more patches which increase in size by spreading at the periphery and leave a perfectly bald area, without any apparent inflammation of the skin. It is one of the less frequent diseases and is met in all walks of life; both sexes and all ages are affected, but it is not so common before 5 or after 40.

Those in perfect health are usually attacked; it may begin insidiously or suddenly, and is confined to the scalp in a majority of cases, although the beard, eyebrows, axilla, pubes, and other hairy parts of the body may be involved. In a few cases, there is a slight burning or itching when the hair begins to fall but, as a rule, a bald spot is noticed on the scalp, without any warning or premonitory symptoms; at first there is usually only one spot, and it may have existed several days before it was large enough to be noticed. Sometimes the hair will fall suddenly, and in the morning a handful of loose hair will be found on the pillow, or it will come out while it is being combed. The patches vary in size, from $\frac{1}{2}$ inch to 2 inches and larger, and are round or oval in shape, but may be irregular, from several patches coalescing or because the disease has stopped spreading in one part.

¹ Read before the Medical Society of the State of New York at its ninety-eighth annual session at Albany, January 26, 27, and 28, 1904.

¹ Read before the Clinical Society of the New York Polyclinic Medical School and Hospital, November 2, 1903.

The hair often falls out rapidly at first and then more slowly, but the patch always increases in size by spreading at the periphery. After a while the hairs may stop falling and the patch remain stationary for some time, then new hairs may appear or the baldness continue; sometimes, however, the hair will commence falling again.

New hairs may appear at the margin, or small fine lanugo hairs will be seen in the patch; these last will often grow to a half inch in length and then fall out, and the process may be repeated several times; again, they will grow stronger and become pigmented, or be replaced by larger hairs with the normal pigment.

The hair sometimes comes in gray and may remain so, but usually becomes pigmented. While this process is going on, new patches are usually appearing and they may coalesce so that finally the whole scalp is devoid of hair.

A few months ago I saw a girl of 8, on whose scalp not a hair was to be seen, except a small tuft about 1½ inches in diameter on the occipital region. Her mother said the disease commenced suddenly, without any premonitory symptoms; first one spot was noticed, then others, all of which increased in size by spreading at the periphery and coalescing until the condition described, which had lasted 6 months, resulted.

Chrysarobin, 2.6 gm. (40 gr.) to 32 gm. (1 oz.) of vaselin, was rubbed in thoroughly every night for 2 weeks; as the alopecia covered so large an area it was applied only to half the scalp one night and to the other half the next. After the chrysarobin was discontinued, precipitated sulfur, 4 gm. (1 dr.), to 32 gm. (1 oz.) of vaselin was rubbed in both night and morning. During the 5 months she was under treatment it was found necessary to repeat the use of the chrysarobin for 4 or 5 periods of a week each in certain areas.

At first, fine white lanugo hairs appeared; these, as a rule, fell out, and were replaced by hairs with the proper pigment.

Recovery was complete, but slow on account of the length of time the disease had lasted before beginning proper treatment. The last time I saw her, no one would know that she had ever suffered from the disease.

In very favorable cases the disease stops after 2 or 3 patches are formed, and new hairs appear either at the margin, or in the bald area; other cases proceed very slowly, taking months before the scalp is denuded; or it extends rapidly over the whole body, so that in a very short time all the hair falls out.

When the disease is progressing, the hair at the margin is thinner, loose, and falls out with atrophied shrunken roots, which Crocker describes as "exclamation points." In some cases there are a few scanty or straggling hairs in the patch affected, but they soon fall out; sometimes a few loose broken-off hairs, resembling those seen in ringworm, may be seen at the margin.

The skin shows no signs of inflammation, and is smooth, shiny, thinner and whiter than normal, slightly depressed, and free from desquamation. If the disease has lasted some time the follicles are to a great extent shrunken so they are scarcely noticed. In recent cases the depression is due to the absence of hair and diminished blood supply, and not to loss of fat, as believed by Michelson; later in the disease, however, there is destruction of sebaceous glands and hair follicles. New spots will often be seen when the disease is apparently disappearing or cured.

A less frequent variety of the disease is when the hair falls out around the border of the scalp, forming a band, which in adults is apt to be more stubborn in responding to treatment.

I expected to be able to show an example of this with this paper, when read.

The woman, aged 34, noticed 3 months ago that the hair commenced to fall out in several spots near the margin of the hair; these spots increased in size by spreading at the periphery; they coalesced, and finally formed a band which extended around the entire border of the scalp.

While this process was going on, 3 small patches appeared on top of the head; there were no premonitory symptoms, and the alopecia was the first thing noticed.

When she was first seen all the spots were smooth, white, shiny, slightly depressed, and not a single hair was apparent; the hairs at the margin were loose, and could be easily extracted.

She was given 2.6 gm. (40 gr.) of chrysarobin to 32 gm. (1 oz.) of vaselin to rub in both night and morning for a week, when the skin became a light mahogany color; it was then discontinued, and a preparation consisting of 4 gm. (1 dr.) of precipitated sulfur to 32 gm. (1 oz.) of vaselin used.

After 10 days it was found that the hair at the margin of part of the area was still falling out, although fine lanugo hairs were appearing in the patches; the chrysarobin was continued for another week, and then the sulfur used. The last time I saw her the disease had stopped spreading, and new hairs were present in all the areas of the alopecia.

The man whom I present to you shows that the disease does not always appear first on the scalp. Six months ago he noticed the hair had entirely fallen out in a small spot on the left side of his beard, and later 3 or 4 other spots appeared; these increased in size by spreading at the periphery, until all the hairs of his beard had fallen out, with the exception of a small tuft ½ in. by ½ in. near the right angle of the mouth. There were no premonitory symptoms.

While this was progressing a small spot was noticed on the scalp over the right parietal bone, which increased in size until it was about 2 inches in diameter; there is another patch, a little smaller, close to this.

Two months ago, when he began treatment, all these spots were white, shiny, apparently slightly depressed, without any signs of inflammation, and entirely devoid of hair.

The small spot about a half inch in diameter over the left parietal bone appeared since he has been under treatment.

On the scalp the hair has stopped falling out, and fine lanugo hairs are present in all the patches. The same condition is seen on the face, except that there are no hairs on an area in the left side of the face about a half inch in diameter.

Particular attention must be paid to the treatment of this area, and there is no doubt but that we can promise him a complete cure.

On the scalp chrysarobin 2 gm. (30 gr.) to 32 gm. (1 oz.) of vaselin was rubbed in thoroughly twice a day; but it had to be gradually increased to 6 gm. (90 gr.) before the desired dermatitis resulted, and the disease stopped progressing. He is now using 4 gm. (1 dr.) of precipitated sulfur to 32 gm. (1 oz.) of vaselin.

On the face it was not advisable to use chrysarobin, and he was given 1 gm. (1½ gr.) of mercuric chlorid in 30 cc. (1 oz.) of alcohol to rub in every night and morning.

There has been a great difference of opinion as to the etiology, some claiming it to be a trophoneurosis, and others parasitic, and again differing as to whether it is contagious or not.

Twenty years ago it was pretty generally considered a trophoneurosis, but gradually the opinion has been changing, and now the majority believe it parasitic, although the other theory still has some strong supporters.

One difficulty has been that the fact has been ignored that patches of baldness may occur with many conditions of the skin, and simply because an area is devoid of hair it should not be called alopecia areata.

Those who claim the disease to be a neurosis, lay stress on the experiments of Max Josephs, who produced baldness in patches upon the ears of rabbits and cats by section of the second cervical nerve near the intervertebral ganglion.

Samuel repeated the experiments and produced an area of baldness, but found there was always an infiltration about the wound, and the hair began to grow when the infiltration subsided. Similar experiments have been made by others with varying results.

There is no question but that there are a number of cases of alopecia occurring as the result of shock or injury to a nerve, but the patches, as a rule, are irregular in shape, and there is not the definite clinical history that we should have in alopecia areata, although they are diagnosed as such by most dermatologists. If these cases were eliminated, as they should be, and classed as "alopecia neurotica," the etiology would not be so much in dispute.

From the clinical evidence there is no question in my opinion but that the disease is parasitic and slightly contagious under favorable circumstances.

If it were neurotic, it would be more common, and would not be so likely to occur principally among those who are strong and healthy and do not show any other neurosis.

The manner of spreading at the periphery, the inflammatory process in the corium, the fact that the loss of

hair does not follow a nerve distribution, and the number of epidemics reported, are decidedly in favor of its parasitic origin. Beside, a portion of a patch may be treated locally and the disease will stop in that area, while it continues to progress in the part not treated.

Although the theory that the disease is parasitic is now pretty generally accepted, there are still some who doubt that it is contagious, although it is generally so recognized in France, and the belief is spreading in other countries.

Many epidemics have been reported, especially in France, occurring in regiments, schools, etc., which in many cases have been ascribed to the use of brushes and hair clippers; also to hat bands, when the same hats have been worn indiscriminately. A number of cases have also been reported in which there is strong evidence that the disease has been communicated.

Hillier reports an epidemic in a parochial school of 1,100 boys and girls; 1 girl had the disease for some time, and then 43 girls, ranging from 7 to 19 years of age, who were associated with her, were suddenly affected.

Ehrenhaft reports an epidemic in an asylum, and Eichoff had 10 patients who were customers of the same barber.

Crocker had 3 cases in which the disease was attributed to wearing hired masks in theatricals; and Feulard, a patient who developed the disease after wearing a mask which a brother suffering from the disease had worn; Morrow, the case of a woman who wore for some time the cap of her brother, who had the disease, and she became affected with it.

Crocker had 8 children in one family with the disease, and after some time the governess noted three bald spots in her hair and consulted her physician, who made a diagnosis of alopecia areata, but told her it was not contagious. She slept with an adult sister, who also contracted the disease. Montgomery had a boy suffering with alopecia areata, and later three younger members of the family were attacked.

Feulard reported, at the Dermatological Congress of 1902, that during the 10 months ending May, 1902, there was an average of 3.3 men affected with alopecia areata out of every 1,000 in the army, and that the number was greater in the larger centers, being 10.6 in Paris. In this country very few epidemics have been reported. Bowen reported an epidemic in which 63 out of 69 girls in a school in Boston were affected.

In some of the reported cases the question may be asked if the diagnosis was correct, but there cannot be much doubt in most of them, if made by skilled dermatologists and the patients carefully examined.

A number of different organisms have been found, but so far none of them has been proved to be the cause of the disease, and all have failed to reproduce it.

There is opportunity to mention only a few. Bazin, in 1862, attributed the disease to an organism, which he called *Microsporon decalvans*.

T. Fox, in 1874, described a fungus composed of very delicate, waxy, mycelial threads. Thin, in 1881, described another fungus, as minute, round or elongated bodies arranged in pairs in the long axis of the hair, which he called *Bacterium decalvans*. Von Sehlen, in 1883, found micrococci in the hair follicle, which were usually seen just above the mouth of the sebaceous gland, although in a few instances, as far down as the papillas.

Robinson, who has made one of the most exhaustive studies of the subject, found cocci in masses and rows, chiefly in the lymph spaces of the corium and in the walls of a few of the bloodvessels; also in the root sheaths of the hair around the affected area. Most of them were present in the middle part of the corium and a few in the papillas.

Sabouraud claims that it is the same bacillus that is found in seborrhea; but the same organism is also found in comedones acne, and although it may be present, it is

no proof that it causes the disease; if so, the disease ought to be much more common. Beside, he claims that it only occurs after puberty, a theory that does not explain the many cases among children.

Crocker believes the disease is related to ringworm, and Hutchinson claims that it is a sort of modified ringworm, in adults occurring subsequent to an attack of ringworm in childhood.

We have many cases of alopecia following ringworm, which are not cases of alopecia areata, and beside, ringworm is such a common disease that if it should occur, it is no proof that it is the cause. We should remember that ringworm and alopecia areata may exist on the scalp at the same time.

Vaillard and Vincent investigated cases from an epidemic affecting 41 soldiers and found micrococci which were closely allied with pyogenic *Staphylococcus albus*.

Roberts suggests that we have 3 organisms: 1. Bacillary alopecia (Sabouraud). 2. Coccogenous alopecia (Robinson, Vaillard, and Vincent). 3. Tricophylic alopecia (Crocker, Hutchinson).

Pathology.—According to Robinson and others, there is an inflammatory process affecting the corium and only slightly the papillary layer, with a round-cell infiltration principally confined to the perivascular system, and an increase in the connective tissue corpuscles of the part. In recent cases only the hair follicles are affected, but in the older ones there is a degeneration, and sometimes entire destruction, of the sebaceous glands. There is a coagulation of lymph in a number of the lymph vessels, and coagulated fibrin in some of the arteries, with thickening of the bloodvessel walls in the more advanced cases. Some of the arteries contain thrombi. Instead of the normal death of the hair, there is a sudden arrest of nutrition which causes the atrophy.

The disease with which it is most likely to be confused is ringworm of the scalp, in which the skin is inflamed, and in old cases there is more or less desquamation; the baldness is not complete, and the follicular openings are rather prominent, instead of being less conspicuous than normal, beside there are the characteristic short broken-off hairs with split ends; the attack is not so sudden, it spreads more slowly, and the scalp is rarely affected in adults.

In doubtful cases the microscope will decide, as in alopecia areata there are distinct signs of atrophy of the hair, and the ringworm fungus is not found.

The bald type of ringworm will give more difficulty, but the microscope and history of the case will usually settle the question.

In favus the history, characteristic odor, and yellowish crusts, incomplete baldness, inflammatory symptoms, irregular patch, and its atrophic character when the crust is removed, should obviate trouble in the diagnosis. The microscope will show the favus fungus in the scabs, crusts, and hairs.

Folliculitis decalvans spreads in an irregular manner, and there are signs of folliculitis with scar tissue.

In lupus erythematosus there is a cicatricial follicular destruction, and a slight inflammatory process.

Alopecia following seborrheal eczema shows signs of that disease, and there is not the smooth bald surface seen in alopecia areata, beside the history will aid in the diagnosis.

Syphilis causes a general thinning of the hair, and there will be other signs of the disease beside the history.

Vitiligo is an affection of the pigment without loss of hair.

Alopecia from röntgen rays: the diagnosis can be made from the history.

Bald areas on the scalp following abscesses should not occasion trouble.

The prognosis is almost always good, provided the disease has not lasted long enough to destroy the hair follicles; it is not as favorable, however, in a patient over

45. If there are only a few patches, and the disease has not progressed rapidly, it is better than when more extensive, especially if it has extended to other parts of the body.

When the occipital portion of the scalp is affected, recovery is slower, and the result is apt to be not so good, as the hair follicles are smaller. One of the patients which I show to you illustrates this:

The boy aged 11, noticed 5 months ago a small area of alopecia on the occipital portion of the scalp, which increased in size until it was about 2 by 2½ inches, a little later another appeared over the left parietal region, which is a little smaller. There were no premonitory symptoms, and when he came under treatment about 2 months ago, there were the characteristic signs of alopecia areata.

Chrysarobin 2 gm. (30 gr.) to 32 gm. (1 oz.) of vaselin was prescribed, but the desired effect was not produced until it was increased to 6 gm. (90 gr.) and this was rubbed in thoroughly every night for a week. It was then discontinued, and precipitated sulf. 4 gm. (1 dr.) to 32 gm. (1 oz.) of vaselin prescribed. After a short time it was found necessary to use the chrysarobin again for a week, when the hair ceased to fall out, and fine lanugo hairs can be seen over both patches, those over the occipital portion not being so strong. He is now using the sulfur preparation, and there is no reason why he should not have a perfect result.

The time the disease has lasted, and the number of downy hairs that have appeared, should be considered.

If a patient has been properly treated for 2 months, and there are no lanugo hairs, the chances are that the hair follicles have been destroyed, and there will be permanent alopecia. It is not unusual to have a recurrence of the disease.

Those, who believe in the neurotic origin of the disease, rely to a great extent upon constitutional treatment, and a number of drugs have been recommended. Duhring and others speak very highly of arsenic, but I have never seen any benefit from its use.

As we consider it parasitic, we depend upon external treatment; however if there is any defective condition of the general health, it should be corrected as in any other skin disease; but aside from this, internal treatment is useless.

The patient should have his own towel, brush and comb. Shaving the head is advocated by some, but the patient is apt to object, and the only advantage is, that it may enable us sooner to discover new lesions; if however, there are a number of patches and the disease is spreading rapidly it is often advisable to cut the hair short.

The loose hairs at the margin should be extracted, as they will fall out anyway, and application can then be better made to the part where the disease is most active. This can be done by taking the hair between the fingers and pulling gently, the loose hairs will come out without causing any pain, leaving the healthy ones.

It is always well to explain to the patient on commencing treatment that the hair will fall out more rapidly at first, as a number of atrophied hairs will come out sooner than if left to themselves.

The skin in the affected patch will stand a stronger application than the surrounding area, and the application should be made beyond what appears to be affected.

Among the large number of drugs that have been recommended are chrysarobin, croton oil, oil of turpentine, oil of cinnamon, carbolic acid, sulfur, pilocarpin, mercury, and lactic acid.

Röntgen rays, Finnsen rays, and radium, have been used, and in many cases have given good results, but the length of time required for the treatment and the cost to the patient are serious objections.

Chrysarobin will give the best results in most of the cases. The patient must be cautioned not to get it in the eyes and it should not be used on the face or over too large a surface at one time. One objection is the discoloration of the skin produced, which extends outside the area to which it is applied. This can be modified by dissolving the chrysarobin in liq. gutta perchæ and then painting on the

patch, but the results are not so good as when used with vaselin. The strength varies from 1.3 gm. (20 gr.) to 8 gm. (2 dr.) to 32 gm. (1 oz.), and depends on the age of the patient and the sensibility of the skin. Children and light complexioned persons require a weaker preparation, and it is well not to use it too strong at first.

The different preparations of chrysarobin vary in strength, so it is necessary to depend on the result obtained, which should be a mild dermatitis, in order to get the benefit of the emigration of the white blood-corpuscles into the lymphatics and destruction of the organisms.

The preparation should be rubbed in thoroughly with considerable friction every night for a week and then discontinued in order to ascertain whether the disease is still progressing.

In chronic cases it may be necessary to use 25% or 50% of croton oil with olive oil, or the surface may be painted with pure carbolic acid, as recommended by Bulkley.

After the disease has stopped spreading, precipitated sulfur 4 gm. to 8 gm. (1 dr. to 2 dr.) to 32 gm. (1 oz.) of vaselin may be rubbed in, and the scalp watched to see whether new patches appear or the hair falls out again in the old ones. If it does or new hairs do not appear, the chrysarobin should be again applied and the same process repeated.

On the face chrysarobin should not be used and in many cases ungt. hydrarg. ammon. or hydrarg. bichlor. .065 gm. to .13 gm. (1 gr. to 2 gr.) to 30 cc. of alcohol gives very good results.

One of the following prescriptions may be rubbed in thoroughly once or twice daily to bring an increased blood supply to the part, which will aid in the nutrition and growth of the new hairs.

Tincture nux vomica	} of each 15 cc. (½ oz.)
Tincture capsicum	
Tincture cantharides	
Castor-oil	7.5 cc. (2 dr.)
Rectified spirits of wine	add 120 cc. (4 oz.)
Oil of lavender	3.75 cc. (1 dr.)
Oil of cloves	15 drops
Aromatic spirits of ammonia	15 cc. (½ oz.)
Rectified spirits of wine	add 235 cc. (8 oz.)
Precipitated sulfur	8 gm. (2 dr.)
Beta naphthol	2 gm. (½ dr.)
Lanolin	8 gm. (2 dr.)
Vaselin	add 32 gm. (1 oz.)

Many of the cases require a good deal of patience on the part of the physician, as well as the patient, but if they are seen early enough one can usually promise a complete recovery.

THE ETIOLOGY AND PATHOLOGY OF ARTERIOSCLEROSIS.¹

BY

H. B. ANDERSON, M.D., L.R.C.P. (LOND.), M.R.C.S. (ENG.),
of Toronto, Can.

Professor of Clinical Pathology and Associate Professor of Clinical Medicine, Toronto University.

In the discussion of arteriosclerosis we will exclude any conditions in which there are changes in the walls of the bloodvessels with narrowing of their lumina, notwithstanding the fact that to some extent they may produce similar clinical phenomena to that disease, but which differ from it in etiology, distribution, morbid anatomy, and clinical course, and confine ourselves to the consideration of the chronic, progressive, systemic disease variously termed arteriosclerosis, arteritis deformans, chronic endarteritis, arteriocapillary fibrosis, and including atheroma. Among the diseases so excluded are the obliterative arteritis of Friedlander, syphilitic

¹ Discussion on Arteriosclerosis, Ontario Medical Association, June, 1903.

arteritis with gummatous infiltration of the vessel walls, periarteritis nodosa, tuberculous arteritis, etc.

Morbid changes in the vessel walls have long since attracted the attention of investigators. Senac (1682-1770), and Morgagni (1693-1770), the father of pathologic anatomy, described such alterations, regarding them as of inflammatory origin. Later, Lobstein (1777-1835), dealt with the subject, and to him we owe the term arteriosclerosis. Rokitsansky, with his almost unlimited supply of postmortem material, examined with great care and detail the alterations throughout the whole vascular system, and his descriptions of the gross appearances presented, stand as the solid foundation on which our present knowledge is based. In his work on "Pathological Anatomy," published in 1846, he expresses the view that the primary condition in arteriosclerosis is an inflammation of the adventitia and media of the vessels, the thickening of the intima being secondary and due to deposition from the blood. Virchow also dealt with the subject, considering the disease to be a chronic arteritis, and pointed out the similarity between it and the slow inflammatory process occurring in the viscera termed fibrosis. On the contrary, Traube (1818-1876), and others, considered the sclerotic changes as secondary to an increased blood-pressure, due to persistent contraction of the arterioles from the presence of certain irritant substances in the blood stream. Traube's ideas received wide acceptance, and continue to be held to some extent at the present day. In this brief historic summary of the development of our knowledge of the disease, the work of Gull and Sutton (1872) is deserving of special notice. These investigators demonstrated the relationship between chronic interstitial nephritis and general arterial sclerosis, emphasizing the fact that the former is frequently but a local manifestation of a systemic disease, affecting both arteries and capillaries throughout the body, to which they applied the term arteriocapillary fibrosis. While these pioneers in this field of research cleared the way for future work, the conception of the pathogenesis of arteriosclerosis generally held at the present time, we owe to the experimental researches and observations of Thoma and his associates. Thoma regards the disease as a morbid process involving the whole vascular system—arteries, veins, and capillaries, to designate which he proposes the term angiosclerosis. According to him, the primary change in the development of the disease is a weakening of the muscular and elastic tissues of the media of the vessels, due to the action upon them of certain general conditions with consequent yielding of the vessel wall to the pressure of the blood. As the amount of blood passing through an artery in a given time is determined, among other things, by the condition of the capillaries, and as these are dilated to a lesser extent than the arteries, the widening of the latter produces only a moderate increase in the amount of blood which passes through them, consequently the rapidity of the blood stream is lessened. This retardation of the blood stream is followed by an increase of connective tissue in the intima of the vessels so as to strengthen their walls, narrow their lumina and thus attempt to restore the normal relation between the caliber of the vessels and their contents. The sequence of events in the development of arteriosclerosis is, therefore, (1) a weakening of the media; (2) dilation of the vessels and slowing of the blood stream, and (3) a compensatory sclerosis of the intima. The increased resistance to the passage of blood through the narrowed vessels may lead to secondary hypertrophy of the heart, in order to overcome this resistance and thus maintain the circulation. It is important to bear in mind that these stages in the process do not occur consecutively in the different parts of the vascular system, but that the weakening and compensation proceed hand in hand, especially in the early stages of the disease.

If, therefore, we accept Thoma's teaching we must regard the thickening of the intima as a compensatory

process, and not the result of inflammation. This conception is of great practical importance because it follows that, being a compensatory process, the sclerosis *per se* is a permanent condition, and therefore uninfluenced by treatment. Moreover, for the same reason, it would be unwise to attempt to remove it even if we had the power. The degeneration and weakening of the vessels with the antecedent causative factors, are the points to be kept in view, the sclerosis is the attempt at repair.

While angiosclerosis is a condition affecting the whole vascular system, still the stress of the causative factors in different cases falls upon different parts, producing much diversity as to the frequency and degree with which particular vessels are affected. For this reason arteriosclerosis is of much more frequent occurrence and shows much more advanced lesions than phlebosclerosis. The latter, however, was recognized by Rokitsansky, and if looked for, will be found to be by no means uncommon. Phlebosclerosis is not only less frequent and less extensive, but especially as the veins do not bear the same essential relation to the nutrition of the tissues that the arteries do, nor are they subjected to as high degrees of blood-pressure, consequently changes in their walls are not followed by correspondingly important clinical and pathologic phenomena.

As to the relative frequency of involvement of different parts of the arterial system, Rokitsansky places first the ascending portion of the arch, then the abdominal and thoracic portions of the aorta. Next in order follow the splenic, the femoral, the internal iliac, the coronaries, the cerebral, the uterine, the brachial and the subclavian. The mesenteric, gastric, and hepatic arteries are seldom affected, even to a slight degree. Sclerosis is also rare in the pulmonary arteries and its branches, and when present is usually associated with long-continued mitral stenosis, emphysema or other conditions with consequent high pressure in the pulmonary system.

Sach, from the microscopic examination of the arteries in 100 autopsies, found sclerosis most common in the arteries of the limbs, and the anterior tibial most frequently affected of all.

It is very instructive to trace the relationship between the various etiologic factors and the relative frequency and extent of arterial involvement. Thus, continuous high tension, increased by mechanical stress, explains the involvement of the aorta and its branches as the coronaries; strain and variations in pressure from muscular action account for the tendency to the disease in the upper extremities of manual laborers; and for similar reasons, as well as from the fact that the vessels of the lower extremities have to support not only the hydrodynamic but also the hydrostatic pressure of the blood, they are especially prone to involvement, the liability increasing, as one would expect, toward their peripheral distribution. On account of variations in pressure associated with digestion, the splenic artery is likewise exposed to the disease. The frequency of the disease in the cerebral vessels is related to the functional requirements of a well-maintained blood supply, increased by occupations attended by long-continued mental effort and worry. The vessels of the kidney, on the other hand are especially exposed to the causes of the disease from the fact that they are brought in contact with toxic substances in process of excretion.

The effects of mechanical strain, etc., are often modified by the selective action which certain poisons appear to have for certain vessels. Thus the toxins of syphilis act especially upon the vessels of the brain, and often of the heart, while lead and alcohol, as well as the toxic products of gout and certain infections, attack particularly the vessels of the kidney.

It is interesting to note, that while mechanical strain seems so potent in its influence to cause angiosclerosis in man, according to Bollinger, horses, dogs, and oxen used

for traction purposes do not develop the disease. A Russian investigator, Ischigajew, who studied the blood-pressure in peasants during the summer months when they were engaged at continuous, laborious work, and during the winter when they were at rest, found that when at work the pressure was increased, but returned to the normal during the period of rest. He compared these results with his observations upon foundry laborers, whose hard work continued throughout the year. In the latter he found permanently high pressure and thickening of the arteries, due to sclerosis. These observations are of importance, as showing the influence of a period of rest in allowing of a return to the normal. The etiologic relation of heredity to arteriosclerosis is well established. Many families show a tendency to arterial degenerations at an early age quite apart from the immediate causes to which they are exposed, "a tendency," as Osler aptly says, "only to be explained by the fact that in the makeup of the machine, poor material was used for the tubing."

From the nature of the causative factors, the tendency to angiosclerosis and the incidence of the disease increase with advancing years. It may, however, develop early in life. In this connection I may refer to a case in a boy

companies, for it is from this class that the largest policies are usually obtained. During the past few years I have examined the urine for a number of companies in cases in which policies of \$10,000 and over were being negotiated, the applicants being men of the class just referred to. They were, as a rule, men considered to be in the best of health and apparently excellent risks. The results are so interesting that I have tabulated the main features in the examination of 30 selected cases (see table).

The coincidence of a high specific gravity, often hyperacidity, a faint trace of albumin, a few hyaline or granular casts or mucous cylindroids, occasionally a few red blood-corpuscles, frequently a deposit of uric acid or oxalate of lime, often excess of indican and commonly a decrease in phosphates, is so frequent as to merit very careful consideration. One might regard the uric acid and oxalates, associated with excess of indican, as suggestive of perverted digestive metabolism, with resulting autointoxication, the casts, cylindroids and occasionally the red blood-corpuscles, being the expression of the deleterious influence of these substances on the kidneys in process of excretion. One may not attach importance to any one of these signs by itself, but the association

of 11, who was treated in the Hospital for Sick Children, Toronto.

Clinically, the child presented all the features of an advanced arteriosclerosis. At autopsy there was found the most advanced and widely distributed general arteriosclerosis with chronic interstitial nephritis. There was no history of syphilis, the only previous illness from which the patient had suffered having been scarlet fever.

The records of a number of such cases appear in the literature. In another case reported to the Toronto Pathological Society by Dr. W. J. Greig, a young woman of 23 had died suddenly. At autopsy the coronary arteries were found so sclerosed that they were practically occluded. No involvement of other vessels was noted.

The strenuous life of financial and business men, particularly stock brokers, men with large interests at stake, with its overwork, worry, prolonged mental and nervous strain, and especially when associated, as it often is, with overeating, alcoholic excess, and with insufficient exercise, furnishes a combination of circumstances that tells particularly upon the vessels, so that it is not surprising that our captains of finance and industry frequently fall victims to conditions associated with arterial degenerations. This fact is of especial interest to insurance

shown by these cases is too striking and too frequent not to have serious significance. It is well known that men of this class are particularly prone to angiosclerosis. Are not these urinary signs, appearing at a time when these persons to outward appearances are in excellent health, signals of danger ahead? They may not indicate a definite angiosclerosis, but I believe they do indicate a systemic condition, which, continued over a number of years, will eventually terminate in that disease. Angiosclerosis is so insidious in its onset, so difficult of early recognition and when once developed, so uninfluenced by treatment, that it is important to take advantage of any means by which it may be possible to recognize cases at a time when prophylactic measures may be successfully employed to ward off or delay an otherwise certain termination.

Just here I should like to refer to the view commonly held by clinicians that a rise of blood-pressure is the earliest indication of the development of angiosclerosis. This is evidently due to Traube's teaching, but apparently is supported on insufficient grounds. A high blood-pressure occurs under two very different conditions in relation to this disease, first as a cause of a certain proportion of the cases, when it will antedate the weakening of the media, the dilation of the vessels and the com-

pensatory thickening. Here a high pressure indicates the existence of a condition that will produce the disease, not the disease itself. In the second condition, *after* the compensatory sclerosis has occurred with narrowing of the lumina of the vessels, and cardiac hypertrophy, there will be an increased blood-pressure, which in this case will indicate the actual existence of the disease. The first condition is remediable, and prophylactic measures are indicated; the second condition is irremediable so far as removal of the sclerosis is concerned. But it is important to bear in mind that other causes beside high pressure may produce weakening of the media and in these cases a high pressure does not necessarily occur *before* the dilation of the vessels and *after* that occurs, the tendency would be for the pressure to be lowered before the onset of the compensatory sclerosis. The early reduction in the quantity of urine is suggestive of a lowered pressure. It is therefore evident that a high pressure is only an indication of the existence of the disease in the stage of sclerosis, a time when permanent changes have already occurred, while it is all important that a diagnosis should be made at the earlier period. Herein lies the importance of the urinary signs mentioned. In the *Lancet* of March 7, 1903, Allbutt refers to this matter as follows: "In sufferers from arterial sclerosis, exorbitant pressures are often but by no means constantly found. Between disease of the arterial tree and blood-pressure there is no direct relation, for even in the extreme degrees of it, normal or relatively low pressures are commonly observed." On this point further observations are required, but it is plain that we are not warranted in looking to a rise of pressure as the first indication of the disease.

The forms in which arteriosclerosis manifests itself have been divided by Councilman into the nodular, the diffuse, and the senile. In the senile form there is atrophy of the liver and kidneys, and in half the cases there is no hypertrophy of the heart.

The diffuse form is met especially in strongly built, middle-aged men. The disease is widely spread throughout the aorta and systemic vessels. Nodular sclerosis is often associated with this form. The kidneys are sclerosed, their surface granular, and the capsule adherent; these organs are often small, but sometimes increased in size. The heart is usually greatly hypertrophied, but from the fact that the coronary arteries are generally involved, the heart muscle shows interstitial myocarditis, and fatty or other degenerative changes. This fact has an important bearing on the ability of the heart to maintain the circulation against the increased blood-pressure. This variety of arteriosclerosis really corresponds with the arteriocapillary fibrosis of Gull and Sutton.

The nodular form is seen especially in the aorta, and, as mentioned before, when advanced in degree, is always associated with more or less diffuse sclerosis. Mott believes that the nodular distribution of the disease is due to a thickening or obliteration of the *arteria arteriarum*, leading to interference with the nutrition and consequent degenerative changes in the parts of the media corresponding to the distribution of the diseased nutrient vessels, with the secondary compensatory fibrosis in the underlying intima. Thoma has shown that these patches do not form projecting buttons during life as they appear postmortem, but merely fill up the weakened spaces in the media. He demonstrated this experimentally by injecting paraffin into atheromatous aortas under pressure equal to that of the normal blood and allowing it to solidify. On removal the surface of the paraffin was perfectly smooth. This is strongly corroborative of his view that the sclerotic changes in the intima are compensatory to a weakening in the media. From deficient nutrition, the sclerotic patches tend to undergo fatty degeneration and softening, beginning in the subendothelial tissue. Subsequently calcification often occurs or the covering endothelium may be shed and an atheromatous ulcer thus form. Thrombi may deposit on the roughened

surfaces thus produced, with subsequent danger of embolism, or the blood may make its way between the coats of the vessel, producing a dissecting aneurysm. It is well to bear in mind that the seriousness of sclerosis is not necessarily in proportion to the extent of the disease. This point is well exemplified in Greig's case previously referred to, in which the sclerosis to gross examination was limited to the coronary arteries. A single plaque involving the orifice of a coronary vessel may be of much more serious import than extensive disease, which does not involve such an essential nutrient vessel. This will also remind us that the condition of the peripheral is no reliable guide as to the absence of disease in the internal vessels.

As to the frequency with which angiosclerosis is found at autopsy, in 1,600 cases at Charing Cross Hospital, it occurred in 380, or about 25%. Bollinger, on the other hand, found it only 136 times in 1,800 autopsies of all ages. In 142 autopsies recently made by me in Toronto, including patients at all ages, I found evidences of angiosclerosis in 83, or about 58.5%. In 49 of these, however, the sclerosis was very slight. Excluding these, sclerosis of a moderate or severe grade was present 34 times, or in nearly 40%. The high percentage of cases of sclerosis in my list is probably explained by the fact that the average age of those in whom it was found was nearly 54 years. It is of practical importance to note the frequent occurrence of emphysema with angiosclerosis. Thus, in 61 cases, Lancereaux found emphysema present 21 times, or in about 34%. In 35 cases of emphysema on the other hand, Gull and Sutton found interstitial nephritis in 21, or 60%. In my cases more or less emphysema was noted in 31%. Of other associate lesions, more or less interstitial nephritis was present in 70%. Hypertrophy of the heart in 43.5% of all the cases, or in 64% of the cases with interstitial nephritis. The coronaries were involved in 41%.

The importance of arteriosclerosis is difficult to overestimate. The dictum that a man is as old as his arteries is fully established by autopsy records.

Longevity, as Osler says, is a vascular question. The more closely we consider the matter, the more clearly we will see how absolutely dependent is the nutrition and function of every organ and tissue of the body upon a proper blood supply. This has been provided by the development of a vascular supply proportioned to the importance and functional activity of the parts. Thus we have arteries, in number and size proportioned to the needs and activity of the part, the caliber regulated by the muscular tissue in their walls, and presided over by the vasomotor system so as to adapt their size to varying requirements; elastic walls to provide a continuous and even flow; capillaries to bring the blood into immediate contact with the cells of the part; and a double system of channels, veins, and lymphatics to return the impure fluids from the tissues. The great force in maintaining the circulation through the system of tubes is the heart. When we consider that in angiosclerosis every one of these provisions for a proper supply is interfered with, we see how far-reaching are the effects of the disease. Thus the heart is hypertrophied and degenerated, the muscular wall of the vessel weakened, the elasticity lost, the lumen narrowed, and the vessel rigid; the capillaries are thickened, degenerated, and more permeable, and added to this, we have the inefficiency of the kidneys to excrete, with resulting toxemia. There must consequently follow a gradual failure of the general nutrition and impaired functional activity in all the organs proportioned to the degree of interference with the blood supply. Merely to enumerate the morbid conditions arising out of or associated with angiosclerosis sufficiently impresses one with the far-reaching importance of the disease. Many conditions commonly recognized clinically as distinct maladies are really manifestations of this protean disease. One may mention fibroid heart, many cases of fatty degeneration

of the heart, chronic Bright's disease, cerebral softening, many cases of cerebral hemorrhage, senile dementia, angina pectoris, Stokes-Adams' disease, senile gangrene, etc. Other conditions closely associated with it are aneurysm, dissecting aneurysm, miliary aneurysm on the vessels of the brain, atheromatous ulcers with thrombosis on the roughened patches, and secondary embolism.

These are all very well-established clinical and pathologic entities, but I wish particularly to emphasize the importance of general nutritional disturbances, the symptoms varying with the seat, extent, and distribution of the vascular lesions, so that an endless variety of clinical phenomena is possible, according as the blood supply to this or that part is chiefly affected.

The occurrence of edemas during angiosclerosis, either spontaneously or from trifling exciting causes, is frequently observed. This is due to the increased permeability of the capillary walls, and to the hydremic condition of the blood found in the disease. Thoma found that he could inject 17 liters of normal salt solution into the normal femoral artery in 192 seconds, before edema developed in the foot, leg, and thigh. In a case of marked angiosclerosis, on the other hand, the same degree of edema occurred after the injection of 4 liters, which, however, took 277 seconds. These experiments would indicate the greatly increased resistance to be overcome in angiosclerosis, and the increased permeability of the capillaries. The occurrence of unexplained edemas should, therefore, suggest the necessity of excluding this disease. For the same reason, spontaneous hemorrhages frequently occur, so that the occurrence of epistaxis or menorrhagia may at times be symptomatic of the condition.

It is also well to remember that in angiosclerosis there is a progressive lessening of the germicidal power of the blood. The subjects of the disease are, therefore, peculiarly susceptible to infections, to which they offer poor resistance, and which consequently frequently terminate the case.

THE DIAGNOSIS OF METAPNEUMONIC EMPYEMA IN INFANCY AND EARLY CHILDHOOD.

BY

JOHN LOVETT MORSE, A.M., M.D.,
of Boston, Mass.

Instructor in Pediatrics, Harvard Medical School; Assistant Physician at the Children's Hospital and at the Infants' Hospital, Boston.

In adult life the signs of pleural effusion conform pretty closely, as a rule, to well-recognized physical laws. The diagnosis of effusion at this age, therefore, is usually not difficult. In infancy and early childhood, however, the physical signs of effusion, especially if purulent, are rarely as characteristic as in adults, and frequently give rise to confusion and errors in diagnosis. A fairly extensive experience has taught me that the physical signs of pleural effusion in infancy and early childhood differ materially from those met in adults, and that the relative value of the various signs is very different at the two ages. Experience has also taught me that unless these differences, which may almost be called normal, are kept constantly in mind, and the diagnosis based on them rather than on the usual signs of adult life, mistakes will constantly occur. I am inclined to think, moreover, that these differences in the physical signs of pleural effusion in early and adult life are not as well recognized as they should be by the profession as a whole.

A pleural effusion following pneumonia in infancy and early childhood is almost invariably purulent. A serous effusion is extremely rare, and if it occurs, almost always becomes purulent later. The physical signs are the same in both serous and purulent effusions, and a

diagnosis between them is impossible without exploratory puncture. The white count is of little use in differential diagnosis in these cases, as both are caused by the pneumococcus, and, therefore, show a hyperleukocytosis. A marked leukocytosis in a case of long duration points, however, to a purulent rather than to a serous effusion. In this article it is taken for granted that the effusion is always purulent.

Onset.—Empyema may develop either during the course of a pneumonia or at some time after the crisis. In the former instance the temperature never falls, while in the latter it rises again after the crisis. In these cases the rise in temperature is usually the first indication of further trouble. In two-thirds of the cases in which I have complete records the temperature never fell, but remained moderately and usually irregularly elevated. In the others it usually rose again within 24 or 48 hours after the crisis. The longest interval after the crisis was 13 days. In the cases in which the temperature never fell, signs suggestive of fluid were found in from 8 to 13 days from the onset of the pneumonia. These were usually not marked enough to justify exploration, however, until several days later. It must be remembered, that the temperature may continue elevated for some time in uncomplicated pneumonia in infancy. In 22 of 61 cases of uncomplicated pneumonia in infants under 2 years of age treated at the Infants' Hospital, the temperature remained elevated more than 8 days—in one staying up as long as 18 days. In these cases, moreover, there was no extension of the process to other lobes. While, therefore, continuation of the fever after the seventh or eighth day should always suggest the onset of an empyema, it is more often, perhaps, due to some other cause, usually located in the lung itself. Acute inflammation of the middle ear also frequently causes a continuance of fever, and should always be kept in mind. In those of my cases of empyema in which the temperature rose again after the crisis, well-marked signs of fluid were almost always present in 4 or 5 days.

Symptoms.—There is nothing characteristic about the symptoms of empyema developing during the course of pneumonia. There is merely a persistence, or possibly an exaggeration, of the symptoms of the pneumonia. They differ in no way from those present when the pneumonia runs an unusually long course; nor is there anything characteristic in the symptoms of empyema developing shortly after pneumonia. They are simply those of any serious pulmonary affection.

The symptoms in cases of long duration, judging from a considerable number of neglected or unrecognized cases seen in out-patient departments or in consultation are, however, to a certain extent, rather characteristic. In all there was, of course, a certain amount of fever, usually irregular and not very high. None of the patients had chills, and none of them sweating. The fact that chills and sweating were absent in these cases is rather an important point and differs from the usual teaching. In fact, in several of these cases, the attending physician had excluded empyema because there were no chills and no sweating. All the patients had some dyspnea, but in many it caused little or no discomfort. Cough was usually complained of, but was rarely very troublesome. The most constant and striking symptoms in all the cases of long duration were excessive loss of weight and marked pallor.

Physical Signs; Inspection.—Inspection of the chest almost always showed marked diminution of the respiratory excursion on the affected side. This point is of little value in diagnosis, however, as the respiratory excursion is also diminished when there is solidification of the lung. Marked diminution is, nevertheless, suggestive of effusion. Evident enlargement of the affected side was comparatively common and is a point of considerable importance in differential diagnosis. Flattening or bulging of the intercostal spaces was unusual and was noted only in the older children. These observa-

tions corroborate, therefore, the generally accepted view that enlargement of the affected side as a whole is more common in infancy than flattening or bulging of the intercostal spaces. The explanation probably lies in the flexibility of the infant's chest, the chest wall in them yielding as a whole instead of remaining rigid and allowing bulging of the spaces as in adults.

Percussion.—In most of my cases percussion showed the usual signs of fluid; marked dulness or flatness on the affected side, often combined with tympany at the apex or at the root of the lung. In several cases, however, there was flatness over the whole side, except at the base, where there was tympany. This occurred in right-sided as well as in left-sided effusions, and once or twice led the physicians in charge of the patients to erroneous conclusions. The tympanitic note is, of course, transmitted from the abdomen, the transmission being favored by the small size of the parts and probably also by the peculiar elasticity of the infantile thorax.

Flatness in Traube's space in left-sided effusions, even when of considerable size, was not nearly as constant as in adults, and was often replaced by tympany. In infancy, therefore, the presence of tympany in this space does not rule out an effusion.

The most constant sign on percussion in these cases was the presence of a marked sense of resistance on the affected side, providing the effusion was of any size. This sign was almost never absent and is, in my opinion, one of the most valuable, if not the most valuable, physical sign in differentiating between pneumonia and effusions. I have never met this marked sense of resistance in pneumonia, and consider it most characteristic of empyema. It is best obtained by striking the chest directly with the fingers or hand.

Auscultation; Respiration.—The respiratory sound was modified in every case but one. In almost all the others it was purely bronchial in character. In only 1 case was the respiratory sound entirely absent. In about two-thirds of the cases it was more or less diminished in intensity, while in a little more than a third it was loud and like that heard over a solid lung. It is a wellknown fact, of course, that loud bronchial respiration may be heard in cases of effusion, especially in early life. I find, however, that this fact is often forgotten or not duly appreciated. In my experience, while the absence or marked diminution of the respiratory sound is important evidence in favor of an effusion, the presence of loud, bronchial respiration counts very little, if at all, against it.

Vocal Resonance.—It is impossible, of course, in young infants to study the vocal resonance from the spoken voice. It must be estimated from the grunts or cries. These have, however, always given me less satisfactory results than the spoken voice. In a general way the vocal resonance varied both in intensity and character with the respiration. There were, however, many exceptions to this rule. Vocal resonance of normal character was not uncommon, and loud, bronchial resonance was even more common than was loud, bronchial respiration. In my opinion, the vocal resonance is of very little importance in the diagnosis of effusion in infancy and early childhood.

Rales.—Rales, usually high-pitched, were occasionally heard through considerable amounts of fluid. The presence of rales does not, therefore, rule out effusion.

Palpation.—What has been said regarding the difficulty of estimating the vocal resonance in infancy applies equally well to the vocal fremitus. In every case in which anything could be made out of the vocal fremitus, however, it was either diminished or absent. The vocal fremitus, if it can be determined, seems, therefore, to be of value in the diagnosis of effusion. It is certainly far more useful than the vocal resonance, and when definite results are obtained, they can be relied on.

Dislocation of Organs; Heart.—Displacement of the heart was present in all but 3 cases. In 1 of these

the affected side was the smaller, and operation showed very marked thickening of the pleura with a comparatively small amount of pus. The heart had probably been pulled back into position by the contraction of the newly-formed tissues. In the others it was presumably held by adhesions. Displacement of the heart was present even when the effusion was comparatively small and was marked in most of those cases in which the effusion was large. The location of the greatest intensity of the heart-sounds changed with the position of the heart, especially in left-sided effusions, and furnished valuable corroborative evidence of the displacement shown by percussion. It seems to me, from the study of these cases, that next to the marked sense of resistance, displacement of the heart is the most valuable sign in the diagnosis of empyema in infancy and early life. Its absence, although it does not positively rule out effusion, is very strong evidence against it; its presence, providing it was not displaced before, is sure proof of effusion in counterdistinction to solidification of the lung, and gives evidence which must never be disregarded.

Liver.—The liver was displaced downward in a considerable proportion of the cases of right-sided effusion. This displacement seemed proportionally greater than that which usually takes place in adults. Before concluding that the liver is displaced downward in infants, it must be remembered that the liver normally extends below the ribs at this age, and that it is frequently enlarged in infancy as the result of disturbances of nutrition. Displacement of the liver, although not as important as displacement of the heart, is very valuable evidence of right-sided effusion.

Spleen.—In 2 cases of left-sided effusion the spleen was palpable. As splenic enlargement is not at all uncommon in infancy, it is very probable that these were enlarged, rather than displaced, spleens. At any rate, splenic enlargement is so common in infancy that very little reliance can be placed on palpation of the spleen in the diagnosis of left-sided effusions.

CONCLUSIONS.

Metapneumonic empyema usually develops during the last days of the pneumonia or during the first days after the crisis, but in rare instances may develop in the early days of the pneumonia, or later during the convalescence. Persistence of the fever and other symptoms after the time of the expected crisis or their recurrence after the crisis should always suggest the possibility of an empyema. There is nothing characteristic about the symptoms of empyema, which are those common to all severe pulmonary affections. Rapid emaciation and progressive pallor are the most constant symptoms in neglected cases, while chills and sweating are unusual. Enlargement of the affected side as a whole is more common than flattening or bulging of the intercostal spaces. Flatness in Traube's space is less constant in left-sided effusions in infants and children than in adults. The most constant and characteristic sign of effusion is a marked sense of resistance on the affected side. Displacement of the heart almost always occurs, and next to the sense of resistance is the most important sign. These 2 signs justify the diagnosis of effusion even if all the other physical signs are inconsistent. Dulness or flatness is almost always present but may be replaced by tympany. The respiratory sound is almost invariably bronchial or bronchovesicular in character, and, as a rule, diminished in intensity. Loud, bronchial respiration is, however, not uncommon, even with large effusions, and counts very little, if at all, against the presence of fluid. The vocal resonance is very variable both in character and in intensity and is of little value in diagnosis. It is very difficult to determine the vocal fremitus satisfactorily. Its absence is, however, an important diagnostic sign. Rales may be transmitted through large amounts of fluid. Their presence does not rule out an effusion.

PURE OLIVE OIL AND ITS USE IN THE TREATMENT OF CHRONIC DYSENTERY AND ALLIED CONDITIONS.

BY

HENRY H. RUTHERFORD, M.D.,

of Fort Mackenzie, Wyo.

Medical Department, U. S. Army.

Pure olive oil is produced as follows: Olives just short of full ripeness, are selected for their soundness and healthfulness, and a moderately rapid and a moderately complete expression made of them. This is done with the utmost regard for cleanliness in every detail. The oily fluid driven away is collected in broad, shallow vats, capable of absolute cleanliness, and is exposed to an even, dry air until all moisture is evaporated. Such a product is pure virgin oil, so-called, a very rare article. If this process is scrupulously carried out with olives grown on foot-hill soil, such as certain districts in middle California, in Italy, and Spain, an oil is produced which for flavor, taste, and color, is most superior of all. This quality of oil, in my opinion, is most easily and reliably obtained from California.

The therapy of olive oil, as given in textbooks, is usually a matter of few words which amount to the facts that it is a good emollient, a slight laxative, and a nutritive, and that it is sometimes given in gallstone disease and is said to act favorably, though it is not well settled by what means it acts. Of recent years, however, a number of observers have advanced theories, founded upon facts, which make the olive oil treatment of certain cases of gallstones, physiologically and therapeutically, a rational remedy. The experiments of Rosenberg have lent most elucidation to the internal action of olive oil, and especially as concerns its effect in the treatment of gallstones. Rosenberg's findings were, in effect, that the oil, which is chemically, in the main, the combined glycerids of oleic, palmitic, and arachic acids, is in part broken up into the original glycerin and acids, together with slight traces of cholesterol, etc., in the small intestines. There the glycerin is taken up and, through the portal system of vessels, reaches the liver and stimulates that organ to throw off increased quantities of a bile which is more watery and solvent of the cholesterol of gallstones. The acids are readily saponified by the alkaline juices of the smaller intestines, and with any remaining neutral oil, absorbed as nutrition. It is along these lines that Dr. McCourt, of New York, Professor Jean Beaumetz, Brockbank, William H. Thompson, and others, have advocated so enthusiastically the olive oil treatment in gallstone disease.

The rationale of this treatment for gallstone disease first suggested to me a trial of olive oil in treating chronic dysentery, sprue, and chronic enterocolitis of tropical origin. The analogy of these conditions and that of gallstone disease may seem far fetched, but on closer consideration it is found that in chronic gallstone disease there is frequently chronic hypertrophy of the liver; in chronic dysentery, etc., there is either a hyperemia or an atrophy of the same organ. These pathologic conditions, moreover, are brought on, in some measure at least, by identical causes—namely, fermentation and putrefaction in the gastrointestinal tract, the absorption of the products of the same, and their conduction through the portal system to the liver, where chronic irritation is caused. More than this, it is a notable fact that in chronic gallstone disease a frequent complicating condition is a catarrhal enteritis caused from long continued lack of bile and the consequent increased degree of fermentation and putrefaction which is thereby made possible. In chronic dysentery the essential and fundamental lesions are chronic ulcerations and necrosis of the mucosa and abscesses of the submucosa of the lower two-thirds of the colon, variable degrees of chronic in-

flammation far up the lining membrane of the small intestines, and in the so-called condition of sprue there is superadded extreme atrophy of the glands and of the muscular walls of the entire gastrointestinal tract, with an apparent denudation of the epithelium throughout. Beside the amebic and bacillary infections of the intestinal tract and their lesions in these chronic wasting conditions, we have to deal with a greatly impoverished general economy, chief features of which are an intestinal digestion and assimilation which is practically nil, an abnormally functioning liver, and frequently chronically diseased kidneys. It is not my intention to attempt a modification of the present accepted etiology of chronic dysentery, but rather to emphasize the importance of having in mind each bit of interdependent pathology when considering treatment, and with this view of the subject favorable results were hoped for from the use of olive oil in chronic dysentery, etc. Accordingly, in April, 1903, permission was obtained from the commanding officer of the United States Army, General Hospital, Presidio, of San Francisco, Cal., and the treatment begun on 10 patients selected for the chronic and intractable nature of their conditions—the majority of them, men who had been lingering in the hospital, undergoing the various routine treatments for upward of 6 months. The method of procedure determined upon and carried out was, for the first 10 days' observation, to make but 1 change in the previous treatments (of these patients), viz., substitution of moderate doses of the purest obtainable olive oil for all other medicines. Hence patients were continued in bed or otherwise, as before, and their diets were not changed, but all previous medicines were discontinued, and instead 30 cc. of olive oil in a half glass of hot milk was given 3 times daily on the empty stomach. At the end of 5 days the dose of oil was doubled in such cases as the quantity could be tolerated, and later still, each individual patient was given increased dosage when it became possible, so that at the end of the first 10 days a number of these patients were taking 90 cc. at the dose. After this 10 days of probation the treatment appearing to warrant further trial, it was decided to continue its use for another week without material change in any particular. At the end of this time there appeared to be no doubt as to the merit of olive oil in this class of cases, and at this hospital the treatment has grown in favor to the practical exclusion of all other medicinal agents formerly in vogue for dysentery, etc.

The special therapy of olive oil as applied to the cure of these chronic conditions is best demonstrated by giving actual case pictures, and in this connection the following cases deemed typical and suitable (for all purposes) are given:

CASE I.—Private M., Irish birth, aged about 24, about 6 feet of stature, and proportionately well developed. His history previous to his present illness is irrelevant. He was originally admitted to sick report with the present trouble on August 7, 1902, and was admitted to the U. S. A. General Hospital, Presidio of San Francisco, California, by transfer from the Philippine Islands, on October 18, 1902. His condition has been diagnosed chronic catarrhal dysentery; complication, chronic parenchymatous nephritis, and on April 14, 1903, was about as follows: Extreme emaciation—weight, 90½ pounds; slight anemia (red cells 3,500,000); complaints of great weakness; constant pain and tenderness throughout abdomen, and bloating and discomfort after taking even small quantities of food. His tongue was heavily coated, his lungs slightly congested from hypostasis, liver dulness was enlarged and distinct, the abdomen distended and tympanitic. The daily bowel movements numbered from 5 to 15, were very disagreeable in odor, liquid and semisolid in consistence and contained large quantities of mucus and muscle fibers. Urine was diminished in quantity, and contained numerous casts, both hyaline and granular. This patient's previous treatment—during the six months, October 13, 1902, to April 14, 1903—had been enemas of 1 to 5,000 quinin solution, 2% H₂O₂ injection, increased daily up to 10%, 1 to 1,000 silver nitrate injection, ipecacuanha and various internal treatments, including tonics. These treatments were tried successively during the period mentioned, each for a month or more, and under what was considered the most favorable circumstances of nursing and hygiene. The

negative result is shown by the following clinical note made on April 14, 1903. Condition has gradually failed since October 14, weight has decreased from 116 to 90½ pounds, and bowel movements numbering as high as 15 in 24 hours, are very disagreeable in odor and contain much mucus and necrotic tissue. On beginning the new treatment this patient was unable to retain more than a teaspoonful of olive oil at one dose, but at the end of 3 days he was taking the full 30 cc. and felt improved. The first positive change was a decrease in the number of daily bowel movements, less pain and tenderness, and a decrease of flatulence. The following clinical note was taken on June 30, 1903: "This patient was placed on the olive oil treatment April 14, 1903. Improvement in his general condition could be noticed in 3 days, and in a week his stools began to form. Since this treatment his recovery has been phenomenal, and in the 2½ months his weight has increased 69 pounds, the character and number of defecations have been absolutely normal since June 6, and he is able to take exercise, and looks the picture of health."

CASE II.—Private R., American birth, aged about 24, about 5 feet 6 inches of stature, and well developed. Previous history is of no importance. He was originally admitted to the U. S. A. General Hospital, Presidio, of San Francisco, Cal., October 13, 1902, by transfer from the Philippine Islands. His condition has been diagnosed chronic amebic dysentery, amebas having been demonstrated in the feces. Condition on April 14, 1902, was about as follows: Markedly emaciated, weight 102 pounds, pale cadaveric facies, slight anemia, complaints of weakness, pain and discomfort throughout the abdomen, the thin walls of which are greatly distended from gas formation. His tongue is thin, narrow and moderately furrowed, with bright red edges. Liver dullness markedly increased. The daily bowel movements number from 5 to 7, are copious, pale gray, of very foul odor and contain necrosed tissue having the appearance of mucus. Intestinal epithelium, muscle fibers, leukocytes, red blood cells and amebas are present. This patient's previous treatment and the results therefrom are set forth in a clinical note taken June 30, 1903, which is as follows: "During the period October 13, 1902, to January 10, 1903, patient lost 14 pounds on the following treatments: Hydrogen dioxide in 2% to 10% rectal irrigations, 1 to 1000 silver nitrate irrigations, quinin enemata of 1 to 500 strength, bismuth subnitrate and bismuth, salol and pepsin. (These treatments were given in separate periods of time.) On January 10, 1903, the patient was put on quinin enemata and, internally, astringent pills. During this treatment he gained 9 pounds, but for 2 or 3 weeks prior to April 14 his condition had been stationary. The oil treatment was instituted April 14, 1903, and since that date he has gained 28½ pounds. His general health and condition are greatly improved, and his feces are normal—becoming so on June 11—although from time to time small quantities of thick, pure mucus are passed at stool."

It has been stated that the curative effect of the oil in the treatment of the conditions of chronic dysentery, etc., is best demonstrated by the case method. This, it would seem, must be supplemented by some theoretic explanation based upon what is known of the physiologic action of pure olive oil and the properties of normal bile, as well as upon clinical observations made in the cases in which the treatment was instituted. Of prime significance are the following facts, which have been learned by experimentation:—

1. The internal administration of olive oil largely increases the flow of watery bile.

2. The normal liquid bile possesses certain physiologic properties: (a) Its presence in the intestine favors the absorption of fats; (b) it stimulates intestinal peristalsis; (c) it acts as an intestinal antiseptic, both directly and indirectly. "Quite recently a further function of the bile has been discovered, namely: That of dissolving very readily certain specific bacteria of a pathogenic character" (Herter). It is still further contended for bile that it has the property of reinforcing the ferment action of the pancreatic juice.

In this connection it is of quite equal importance that following upon the internal administration of olive oil, typical cases of chronic dysentery, practically without exception, show changes in their condition as follows:

1. Positive evidence of increased quantities of bile in the feces.

2. Decrease in the number of daily bowel movements and marked improvement in the character of the same.

3. Gradual cessation of signs of fermentation and putrefaction along the gastrointestinal tract and consequent subsidence of pain and tenderness.

4. General systemic improvement—gain in appetite,

repair of digestive facilities, symptoms of improved nervous system, and rapid gain in weight and strength.

5. Apparent positive cure after an average time of 2 months and upward, with few recurrences up to date.

Is it not fair to infer that olive oil of this pure variety is cleansing, protecting, and soothing to inflamed mucous membranes; that it restores the liver, which is almost functionless in the chronic wasting diseases, to its normal activity as an excretory organ; that the improved quantity and quality of bile which reaches the duodenum¹ produce directly or indirectly a more or less specific effect, not only upon the local pathologic conditions, but upon the general systemic pathology in these cases? And aside from all these worthy hypotheses, must it not be granted that, in the digested oil, we have a most highly desirable heat-producing nutritive for such class of patients? In this connection it would seem pertinent to quote from a review of the researches and observations of Charrin, "On the Multiplicity and Complexity of the Soluble Products Developed During the Course of Infections," in which it is stated that "a characteristic of recent progress in medical sciences is the growing importance accorded to the organism itself, the rôle de l'économie, in the genesis of pathologic conditions. We have already partially restored the 'soil' to its old predominant place in the etiology of disease. We recognize the predisposition afforded by getting chilled, overexertion, inanition, etc., and the organism is coming into its own in this respect more and more every day. For instance, in very young infants, the disturbances consecutive to chronic gastroenteritis are due, in certain cases, to the insufficiency of the intestinal defenses. During the acute stage the numbers or the virulence of the poisons engendered in the digestive tract are responsible for the symptoms observed, but in many cases, after this stage is past, the poisons are found to be no more active than those elaborated in the normal infantile intestine. This peculiarly deleterious action is due to the lack of protection against them. The direct or indirect action of the tissues and of the physiologic apparatus in the mechanism of morbid phenomena is becoming more manifest every day. Cellular pathology is resuming its rights, not altogether Virchow's old cellular pathology, but a conception singularly enlarged. The idea that a microbe engenders disease by the action of its toxin is being shown up more and more to be altogether too limited and inadequate to conform to what we are learning in regard to the multiplicity and complexity of the soluble products elaborated during the course of an infection by the interaction of bacteria and the cells of the organism. Immunity is only a special phase of nutrition, the consequence of these interactions."

Upward of 75 patients in all have been treated by olive oil in the service of the United States Army General Hospital, Presidio of San Francisco, Cal., and from this experience the system of the treatment evolved is as follows:

First Period.—The patient is given 30 cc. of oil three times per day, for the first 3 days, when the quantity is increased to 60 cc. three times daily, and on the sixth day is again increased to this quantity four times in 24 hours. During the first half of this period the patient is to be given only a milk diet. The latter half he will have added 1 to 3 ounces of scraped beef or its equivalent of egg albumen daily.

It will be found during this period that the patient's system gradually comes to a tolerance of the oil; individual cases varying according to their peculiarities and the gravity of their conditions. Quite frequently during this period, patients lose in weight, but this is a temporary incident, due to the obvious causes of restricted diet and anorexia at beginning of treatment.

Second Period.—Oil can now be given in greater quantities (not less than 90 cc. three times daily, without discomfort to the patient) and must be kept up for a length of time as *res necessitante*, in severe and extremely chronic cases, perhaps for 2 months or more, during which period convalescence will have

been fully established, and the patient regained his normal weight.

Third Period.—During this, the getting up period, the patient is gradually restored to a full diet, and the oil is given in gradually decreasing doses, until it is insured the pathologic conditions have been obliterated (ulcers fully and permanently healed), and a recurrence is not liable.

During all of the first period, and a greater part of the second, the patient should be kept strictly in bed, and required to use the bed-pan until stools have reached a solid consistency.

It is found, in most cases, in giving oil, that until a patient acquires a tolerance for it, it is best taken with about equal quantities of hot milk. Cold oil and hot milk, being about the same specific gravity, will for a short time (a half minute) mix so perfectly as practically to form an emulsion. Later on, without an exception, it is found that the patients acquire a relish for and can take oil in any reasonable quantities at least four times a day. The oil is given about an hour before meals, so as to get the maximum effect on the empty stomach, intestines and liver. The oil must be pure virgin olive oil.

For assistance, during the experimental stage of this treatment, I am under obligations to Major W. P. Kendall, Surgeon, U. S. Army, commanding officer of the hospital; Captain J. W. Kennedy, assistant surgeon, U. S. Army; First Lieutenant R. B. Grubbs, assistant surgeon, U. S. Army; and Miss Sibbie Wilson, Army Nurse Corps, U. S. Army.

The first 24 cases recorded as treated were in the service of Dr. Grubbs.

To the Commanding Officer, U. S. A. General Hospital, Presidio of San Francisco, California: I have the honor to report as follows on the article referred to me relative to the olive oil treatment of dysentery. After a careful review of the first 28 completed cases of olive oil treatment to come under my observation, I find the results to be as follows:

Returned to duty, 17 patients. These, with 2 exceptions, had every appearance of good health, and laboratory reports for a month previous to discharge, showed nothing abnormal in the condition of stools. One having 4 stools to 5 stools, was returned to duty to accompany his regiment east; another had, at times, traces of blood and mucus in his stools. Three left the hospital by reason of expiration of service, one in good condition, the other two having from 2 stools to 5 stools per day, one of these still showing amebas present, although about 3 months under treatment. Seven were discharged on surgeon's certificate of disability. One of these patients had but 2 months' treatment, the remaining six from 3 months' to 6 months'. At the time of discharge, all were having from 3 stools to 6 stools during 24 hours. One patient, supposed to have been cured, developed appendicitis, and during convalescence from the operation, had a recurrent attack of dysentery.

Private R., mentioned in the paper, was discharged September 24, on surgeon's certificate of disability, having 3 stools to 5 stools per day, frequently fluid. Amebas were last found July 8, which would indicate that there had been a relapse. This patient was on the oil treatment for 5½ months.

Of the patients mentioned, six had rectal irrigations in connection with the oil treatment. All had a tonic, usually the elixir ferri, quinin, and strychnin.

In considering the value of the treatment, it must be taken into consideration that many of the cases were of long standing, and had reacted poorly to the established line of treatment, and were transferred to the ward for the purpose of testing the oil treatment.

The statement that the number of bowel movements is immediately decreased, while true in the majority of cases, is not, in my judgment, due so much to the specific action of the oil, as to the fact that the patient is put to bed and given a suitable diet.

The fifth statement, as to the "apparent positive cure, after an average time of two months and upward, with no recurrence up to date," would, in my opinion, seem a little premature, as I think it is generally admitted that recurrent attacks are frequent a year or more after an apparent cure in cases that have advanced to an ulcerative stage in the bowel.

Even with this adverse criticism, I heartily approve of the oil treatment, but I believe the benefit derived from it to be principally due to the fact that it is an easily assimilated food. It is not unusual for patients to gain 30, or even more, pounds per month, and with this increase of weight there is a proportionate gain of strength and general vitality. It stands to reason, that as nutrition is improved, the system is better prepared to combat with the degenerative changes occurring in the alimentary tract. I consider the oil treatment, combined with quinin irrigations, if amebas are found, or silver nitrate when ulceration exists in the large bowel, to be the most satisfactory that I have tried. At present I am treating about 35 patients

with dysentery with oil and irrigations, with very satisfactory results, but do not think we should claim positive cures in any case of amebic dysentery in which the pathologic condition in the intestine has progressed to the ulcerative stage, until the cases have been followed from 1 to 2 years' time after apparent cure, as it is a well established fact that recurrences after long intervals of good health are frequent in these conditions.

G. PARKER DILLON,
Contract Surgeon, U. S. Army.

THE MIND AS A CAUSATIVE AND THERAPEUTIC FACTOR IN MEDICINE.¹

BY

BITTLE C. KEISTER, A.M., M.D.,
of Roanoke, Va.

In this age of scientific progress the attention of the medical profession seems so enthusiastically engrossed in microscopic pursuit of the wicked bacillus, the absolute and immediate excommunication of the appendix vermiformis, and the mechanical adjustment of bone deformities by the Lorenz method, that the mental factor in medicine has become almost obscure and obsolete.

Strange as it may seem, but few of our modern textbook writers on therapeutics make any mention of the mental side of medicine, yet every other possible, and I may add, impossible, aid to therapeutics is gravely discussed at length—including obscure organic extracts from nearly every glandular organ of the body of both man and beast; also the various and peculiar forms of exercise of the muscular and glandular systems, under the names of mechanotherapy, massage, calisthenics, Swedish movement, mountain climbing, mud baths, foot-racing, etc.; also every variety of light, heat, and röntgen ray; and also patent foods of every conceivable formula and trademark—while scarcely one line is devoted to psychotherapy.

If we turn from the textbook to the class-room or hospital, we find the same result. Students listen with rapt attention to the latest methods in antiseptics, the culture of microorganisms, the use of antitoxins; they study the powers of many well-advertised drugs; they discuss keenly the rival merits of the diverse forms of splints, sutures, forceps, inhalers, anesthetics, and various instruments of precision, and the best methods of diagnosis. All these necessary and important factors in therapeutics are thoroughly exhausted, while at the same time the omnipresent mental factor is almost universally ignored.

We may attend clinics on functional nerve diseases in which the mental factor is predominant both in cause and cure, and though listening for an hour to the physical signs established by tendon and skin reflexes, with trained and systematic observation, fail to hear one thing to show that the disease has had other than a purely physical origin, or that it can be cured by other than purely physical means.

Turning from the teaching to the practice, we cannot fail to see the natural result. That which is ignored in physiology is not likely to be admitted in pathology; what is never taught in the clinic is not often practised in the sick-room.

While the influence of the mind over the body, as well as mind over mind, is everywhere seen and felt, it is at the same time neglected and ignored in hospital wards, in consulting-rooms, and by sick beds, and hence the amazing spectacle so constantly seen of men laboriously trained in all the medical wisdom of the twentieth century, patiently investigating the causes of diseases, or earnestly considering methods of cure without a thought of the ever present mental factor; and sometimes hardly realizing that the case is that of a suffering human being, but regarding the patient more as an object similar to a

¹ Read at the fifty fourth annual meeting of the American Medical Association, held at New Orleans, La., May 5 to 8, 1903.

machine that is out of order and in need of a mechanical engineer to adjust or arrange the machinery.

It is becoming quite common in medical literature to forget that a man as such still exists, while it is perfectly obvious that whole lives apparently center round the appendix, the posterior nares, and the ubiquitous mosquito. Sir James Paget well said: "A physician's exclusive duty should be to study men as men, to master the marvelous intricacies and dependencies of spirit, soul, and body, and to be sufficiently skilled to know when and how to call on the one to help the other, and with such men the profession would be complete."

Dr. Alfred T. Schofield, of England, says: "The mind is the most important factor in any or all diseases to be considered," therefore the practitioner should remember this factor when dealing with obscure cases of dyspepsia, malassimilation, flatulency, gastralgia, nausea, dyspnea, syncope, etc.

In spite of the general apathy of which I have complained, the psychologic side of disease is recognized by some of the ablest writers and foremost leaders of the profession, among whom I may mention such men as Clouston, Gardinier, Tuke, Schofield, Gowers, Church, Brower, Mann, and S. Weir Mitchell.

Sir Benjamin Brodie remarked: "It is the business of every practitioner of medicine to study, not only the influence of the mind on the body, but also that of the body on the mind." A debilitated condition of the body may produce a weakened state of the intellect.

Dr. Lockhart Roberson points out "that all who are engaged in the healing art must sooner or later learn to search out and understand the mental and moral, as well as the material causes of disease."

Sir James Brown says: "Medical psychology belongs to our whole medical profession, and no medical practitioner can afford to ignore the fact."

Among the many causes of mental and nervous diseases, and their increasing prevalence over all other diseases of this age, may be cited the increasing demands made on the brain powers in the effort to achieve fame and fortune, regardless of the pathologic effects on the brain centers. Another prolific cause of brain disease, intellectual weakness, and nervous prostration may be traced to the high pressure process of our public school systems, the effect of which may not become manifest or even noticeable until later in life.

Neurotic affections of both children and adults are rapidly increasing and multiplying with our civilization. The increasing nervousness of this age is most clearly evinced by the connection with, and influence of, the nervous system on other diseases of the body, not properly nervous in their character. In diabetes, for instance, the nervous system is in intimate relation, and this disease is often induced by mental anxiety and distress, or by sudden fear or shock. This disease, also Bright's disease, nephritis, granular kidney, cancer and heart disease are all on the increase in the ratio of the increase of nervous diseases. The sympathetic system, which is largely controlled and influenced by mental emotion, causes functional diseases of all the parts, inflammations, many organic diseases, edema, exophthalmic goiter, angina pectoris, headache, jaundice, and neuroses of the various organs.

Dr. Sansom, in the "Twentieth Century Practice," says: "Mental shock and protracted anxiety are prolific causes of morbid conditions of the arteries, producing arteriosclerosis, a disease that has become very common of late years among doctors, politicians, and financiers. The emotion of anger is capable of increasing the blood-pressure from 14 cm. to 21 cm., and the corpuscles from 3,000,000 to 4,500,000 per mm."

Dr. Jno. Hunter remarked that atheroma, apoplexy, and angina pectoris have long been known to be caused by emotional excitement.

The intellect can influence and produce indirectly hyperesthesia, anesthesia, paresthesia, and all varieties

of special sensation. It can contract and relax muscles and cause both voluntary and involuntary movements. Dr. Murchison said "he was utterly surprised to find so many cases of primary cancer of the liver, uterus, breast and other organs, caused by prolonged grief and anxiety." Dr. Bennett tells of the increased growth of fibroid tumors following constant worry. The mind is a potent factor in contracting infectious diseases. It is a well-known fact that physicians owe their immunity far more to this fact than to any special care they take of their persons toward warding off these diseases. Professor Rolliston points out the wellknown fact that after a defeat in battle, an army of healthy soldiers readily succumbs to dysentery, scurvy, malarial fever, etc.

Sir James Paget tells of a young man who had hemoptysis on his birthday for 9 consecutive years, being quite free during the intervals, but who died of rapid pulmonary tuberculosis after the tenth anniversary. We might continue narrating instances in which the mind is the causative factor in disease, both functional and organic. We might also show how our civilization and modern modes of living are producing mental and physical weakness by the various agencies at work under the sanction of law. The conditions of modern life which act on our complex and excitable nervous systems have much to do in bringing about phenomena that perplex the physician in reaching a diagnosis and formulating a suitable course of treatment.

As previously mentioned, our modern systems of education are also influential in promoting nervousness and in contributing to the increase of mental diseases. The general tendency of modern education on the young is to increase the activity and susceptibility of the nervous system by modifying the nutrition of the brain centers and overstimulating their growth; and in fragile, sickly, or badly-nourished children inducing brain exhaustion, cerebral anemia, hysteria, and finally organic diseases. Growth must precede function, and if while the child is so young or delicate and the functional activity still feeble, we apply undue exercise or stimulation, the brain powers will never be brought to their highest degree of development. The whole future complexion of mental life is, in great part, determined by the impressions made on the sensory centers of the brain when they are undergoing development.

From a therapeutic standpoint we must aim in our systems of education at a harmonious development of body, brain, and mind alike, and we shall then attain progress and health combined. After careful study and a thorough analysis of all these important facts, with their pathologic bearing toward bodily ailments, we can readily see why the mind is in such intimate relation to the body.

Psychotherapeutics is an important branch of medical science, and is apparently in its infancy. Its power for good in the hands of the educated physician was never more pressing than at present. There can be no doubt that if the mental factor in medicine had been properly recognized, studied, and taught by our predecessors in medicine, quackery, witchcraft, faith cures, osteopathy, eddyism, etc., would never have attained the position they hold today.

The modern doctor must understand the pathology and hygiene of the intellect if he would be successful in his cases of neurasthenia, hysteria, and the many other functional nerve diseases.

The neglect of the mental factor in medicine is a source of unpardonable weakness on the part of the medical profession. Our failure to appreciate this important fact in the past has been the one prolific cause of so much skepticism on the part of the laity, and has driven millions of our good paying and intelligent patrons to seek relief at the hands of uneducated fanatics and quacks, who play their role under the guise of Christian science, osteopathy, faith cures, etc. We must take a full share of blame for this state of affairs, and endeavor

to make amends in the future for our neglect in the past.

If it is possible or even probable that such persons as Mrs. Mary Baker Eddy and Mr. Alexander Dowie, and others of less repute of their kind, can cure disease through the influence of the mind, why should not educated physicians make use of this mental factor in medicine?

There have been undoubted cures of both functional and organic diseases wrought through the mind by these so-called religious fanatics. If there had been no cures, their theory and so-called science would long ago have died and been buried in oblivion. Instead of this, however, Mrs. Eddy boasts of a clientele of over 2,000,000 Americans, and an equal number of English. In New York City Mrs. Eddy has a church that cost over \$100,000, and it is crowded every Sabbath with an educated class of people, who pay both homage and money to their apostolic healers to be cured of their bodily ailments.

Chicago has been turned almost upside down by one of these spiritualistic fanatics, who has the walls of one of the largest halls in the city decorated with crutches, canes, and splints presented him by cured patients and patrons.

These wonderful and mystifying cures are vouched for by the healed in every section of the country, and while they cannot be explained by physiology, yet they are nevertheless true. Eddyism shows plainly how the mental factor can be utilized by charlatans, who continue to reap golden harvests from their followers, while the educated physician, with all the scientific training and modern equipment that can be afforded him, stands off in silent amazement, exclaiming "what fools they are!" Dr. Schofield says: "While most men are fools, still cures are effected by not only respectable quacks, but the most arrant knaves, and testified to by respectable people, including the clergy." Many of these cures are not lasting, many are trivial, but many are complete. We have distinguished men and professors in the medical profession, such as Charcot, of France, and many of honor and repute in our own country, who testify to cures of all sorts and kinds without medicine or physical means. All this may appear to some as a "riddle" of the most perplexing kind, and when the last echo of the laughter of derision and the last curve of the smile of contempt have died away, there remains much to make the conscientious physician of this age ponder, think, and act.

In my judgment, every recognized medical school in this country should have a chair on psychotherapy, including under this head psychophysiology and psychopathology.

Until this is done we need not expect to attain to the full function of our noble calling, nor obtain the honor that rightly belongs to medical science.

Lay Sentiment on Physicians' Charges.—With regard to the enormous fees sometimes charged for attendance on wealthy people, to which so much exception is taken by persons who have nothing whatever to do with the matter, we can see no good reason for finding fault with them. Suppose the patient is a millionaire, who spends hundreds of thousands yearly on the mere pleasures and luxuries of life, and who cannot possibly get more out of existence than he does. When illness attacks him all the delight of life vanishes and his money is powerless to help him. With death staring him in the face he would gladly give half his wealth to any one whose skill could avert death and restore him to health; but no physician drives such a bargain with him in his dire extremity; and, after all, the largest bill ever yet sent in, is small compared to what the patient would pay to a lawyer for gaining a suit, or expend on one or other of his costly pleasures when he is in health. To the honor of the profession, be it said, there are very few instances on record of large fees being charged to those whom the doctors knew to be in such circumstances that it would be difficult for them to pay them; while hundreds of instances are known of the most generous treatment of patients in poor circumstances by men who are in the habit of receiving large sums for everything they do.—[*Charleston (S. C.) News and Courier.*]

A COMPARATIVE STUDY OF ANIMAL BLOOD.

BY

EDWARD T. WILLIAMS, M.D.,
of Boston, Mass.

The first scientific classification of the animal kingdom was that of Aristotle (384-322 B. C.),¹ who divided the animals into 2 classes, the blooded and the bloodless. It was subsequently ascertained that the so-called bloodless animals had colorless blood, which led to the substitution of the terms red-blooded and white-blooded in place of the original nomenclature of Aristotle. Still later it was discovered that annelid worms (leeches, bristle-worms and earth-worms) were possessed of red blood, which led to the entire abandonment of the old classification and the adoption of the words vertebrate and invertebrate.² But this change of names did not alter the general truth that the blood of the vertebrates was for the most part red, while that of the invertebrates was white. Finally Cuvier³ subdivided the invertebrates into 3 sub-kingdoms, articulates, mollusks and radiates, to which modern zoologists have been compelled to add 1 more, the protozoans. It has also been ascertained that there are no hard and fast lines between any of these groups; intermediate and transitional forms occurring everywhere as connecting links between the various classes.

In the lowest animals, the protozoa, we find nothing which can properly be called blood. The one-celled organisms, like the ameba, absorb nutriment and disgorge the waste products by the simple process of imbibition and exudation. Yet the contents of the cell are frequently seen to be in motion, often of a rotary character. In the many-celled organisms the nutritive juices are passed on from cell to cell, like the sap of plants.

The radiates are more doubtful. Most of them, like the sea-slugs (holothuria), sea-urchins (echini), and star-fishes (asteriades), are permeated with water-vessels, generally connected with the intestinal canal, through which the products of digestion (chyme), mingled with sea-water, are carried to all parts of the body. They are supposed to perform the double function of supplying the tissues with nutritive elements and oxygen, and of carrying off excretory products. So far as I can learn, there are no clear evidences of a blood system in radiates.

We now come to certain marine worms which seem to form a connecting link between the protozoa on the one hand and the articulates, mollusks, and vertebrates on the other. Some of these forms are distinctly segmented like the annelids, others have shells like the brachiopods (lamp-shells), while the ascidians (sea-squirts), whose anatomy and development have been particularly studied by Kowalevsky and Kupffer are possessed of a true notochord, which unmistakably connects them with the lower vertebrates.⁴ Nearly all these worms have a heart, a closed system of blood-vessels and a true blood, which in all except the annelids, is colorless, and contains ameboid corpuscles precisely resembling the vertebrate leukocytes. The blood of the annelids is red, but this is simply its natural color, and not due to the presence of red corpuscles as in the vertebrates.⁵

The mollusks, I believe without exception, have hearts and bloodvessels, and a white blood with ameboid corpuscles.

The articulates vary. The marine forms, like lobsters and crabs (crustacea), have a well-developed heart and bloodvessels, and a white blood with ameboid corpuscles, like the mollusks.

In the insects the blood system is comparatively rudimentary, while the breathing apparatus is enormously developed. The body is completely permeated with air tubes communicating with a system of dilatable air sacs, which not only furnish the tissues with oxygen but give lightness and buoyancy to the frame.

The last of the series is the lancelet (amphioxus), which though always classed as a vertebrate, has no backbone whatever. Its place is supplied by a cellular notochord, like that of the ascidian, or the young vertebrate embryo. The blood, moreover, is white, and contains white corpuscles.

The true vertebrates have 2 kinds of blood, white and red. The white blood, which is strictly homologous to that of the invertebrate animals, consists of lymph and chyle, with their peculiar cells. These fluids contain albumin, fibrin, and salts in the same relative proportions as the red blood. The red blood is simply lymph, enriched with vast numbers of red and white cells from the spleen and bone marrow.

This conception of the blood is by no means new. It is clearly foreshadowed by numerous authors, among whom I may include Carpenter⁵ and Chauveau.⁶ It would seem, however, to be completely ignored by the new school hematologists.

THE SCIENTIFIC BASIS OF MIND CURE.

BY

SELWYN A. RUSSELL, M.D.,

of Poughkeepsie, N. Y.

"Thoughtless people contradict as readily the statement of perceptions as of opinions, for they do not distinguish between perception and opinion. They fancy that I choose to see this thing or that thing. But perception is not whimsical, but fatal. If I see a trait, my children will see it after me, and in course of time all mankind, though it may chance that no one has seen it before me. For my perception of it is as much a fact as the sun."—Emerson.

Being a patron of *American Medicine*, I have from the first felt a deep interest in its pages, and especially have the editorial columns had an attraction for me, for in them I see the editor and become acquainted with his personality, and learn his views upon the various questions of interest to the medical man. I have noticed, however, not without a degree of amusement, the effect on this most excellent journal of the literature (save the mark!) emanating from alleged mind cure sources, an effect somewhat like that of a red rag shaken at a bad-tempered bull! For, according to the editorial comments, there is in it not only no good, but it is an evil unmixed and unmitigated. Much of this alleged literature is indeed off-color, and though not exactly yellow, nor precisely blue, it may be said to combine the two.

This so-called New Thought literature really has in it much that well might excite to wrath, laughter or tears, according to the reader's point of view. Surely the ignorance so often displayed is pitiful, the assumption ridiculous, the occasional mountebankery offensive. That most of these misguided folk are for the most part moved by good intentions cannot be doubted (it is the pretenders who are objectionably blatant), but good intentions are not enough; knowledge is as necessary as integrity. The persons who write on this subject are generally such as have been cured of some disease by mental treatment, and this single fact generally is the only one which entitles them to a hearing. They usually have made no study of the subject, properly speaking, and too often they are not students in any sense. Hence, it is not strange that they see this single fact altogether out of focus, nor that they should have extravagant notions of its importance. Being men of one idea, that single idea is in a measure wrong, for it is not correlated with other ideas, and therefore there is no perspective, no means of estimating its relative and therefore its proper value. But we must accept the initial fact of cure, the alleged facts and illogical inferences must often be either rejected or accepted with great caution. Although we are bound to reject what is false, we are under the same bonds to accept what is true, which applies as much to Christian science as to the other forms of mind cure.

Assuming, for the sake of argument, that these folk though evidently misguided are generally honest, we may at least accept their statement as to the fact that they have been cured of something, though it may not be what they say or in the

manner they describe; but these two possible errors may be due (1) to their ignorance of disease: (2) ignorance of psychology, and (3) ignorance of therapeutics. Admitting that they have been cured of something, if their explanations do not convince us of their truth we may investigate for ourselves. Their ignorance of pathology and therapeutics is more excusable than their ignorance of the English language, but at neither of these need we feel surprise or offense.

Even their alleged facts show great carelessness of observation, classification and recording, so that what they really have experienced is often most difficult to get at. But they have seen something; they have had a vision, and this vision has been to them a sort of "revelation." They regard it in that way, which is especially true of Mrs. Eddy. This "perception" of something "is as much a fact as the sun;" their whims and notions do not invade here. They have seen a fact in nature, and not being able to classify it, it has classified them. But partial as they are, they are perhaps not more so than the specialist in medicine who sees in one organ the cause and cure of all the ills that flesh is heir to.

Seeing disease actually cured by mental means is a great and significant mystery to them, is really miraculous, and they are consequently led into all sorts of extravagant and ridiculous statements. But we must handle the fact with care, and reverently, and try to discover exactly what it is and where it belongs. For facts are stubborn things, and must be reckoned with, and it matters not so much where found or how much mixed with error, it is the duty of the man of science to rescue them from bad company. As the diamond is still precious though found in the gutter, so a fact is still a divine thing, regardless of any possibly bad associations, and it is, therefore possible that even Christian science and other forms of mind cure may still have in their bushels of chaff some grains of genuine wheat.

It is the truth we want, and though it may be difficult to sift it out, it is not impossible, and the task may have its compensating rewards; and the task will be all the easier if we approach it without prejudice or prepossession, but with the determination to see exactly what it reveals, and to recognize and accept it notwithstanding its besmirched appearance or its seeming inconsistency with previous ideas. Truth survives all sorts of bad usage, and its best feature is that it only shines the brighter because of it. We are not in sympathy with our orthodox friends who seem to think it sacrilegious to subject what they denominate revealed truth to any test of accuracy, as if any truth were too sacred for examination or criticism. Truth may be bandied about in the most irreverent manner, or even flung away as worthless or positively harmful, but it not only survives such treatment, but seems all the more brilliant for such misuse.

"Truth crushed to earth shall rise again;
The eternal years of God are hers."

And so we come at last to have a great reverence and love for the truth, indeed, the honest man feels that he can safely worship at no other shrine. This love of truth makes him very jealous of it, and begets in him a desire above all things to see it justified, that it may have its deserts and prevail.

Fully aware of these general truths, and with all due deference, may we not reverently rake over what has been irreverently called the "rubbish" of Christian science in the hope of finding some compensation for our trouble? The Christian science folk very wrongly claim that their cures are positive proof of the correctness of their theories, and all their theories. But with the same sort of reasoning we should have to admit that the cures wrought by the various other forms of mind cure (faith cure, divine science, animal magnetism, osteopathy, the water of Lourdes, etc.) are equally positive proof of the theories given in explanation of them. For all these have cures as certain and theories as positive. The scientific man, quite willing to accept the fact of cures, is equally unwilling to accept the explanations. Even Christian science itself, while claiming the correctness of its own theories, at the same time denies the correctness of the others' theories, arrived at by the same process of reasoning. But most of the theories formulated to explain the facts are manifestly impossible. Not-

withstanding this, is there not some underlying fact or factor, unrecognized by these partialists, persons of one idea, which may rationally account for the cures? Without doubt there is.

There are several points of view from which mental treatment appears not only rational, but inevitably necessary; also from which it is equally clear that medical treatment is not only irrational, but doomed to failure. It should be possible to make these points so clear as to leave no doubt that mind cure stands for a truth easily demonstrated by facts. If such demonstration is not possible, mind cure is without scientific basis and unworthy the study of thoughtful men.

Plato has been called great because he saw that every question has two sides, and although the present plea is for the admission of mental conditions as factors in the cause and cure of disease, I disclaim any wish to ignore physical causes or minimize their importance. Excess of skepticism is as bad as excess of credulity, and the aim of this writing is to show that it is just as necessary to admit facts in the domain of mind as in that of matter. While we are not yet able to get on without medicines, which seem still to have a limited use, the more study we give to the origin of disease the more potent and far-reaching seem mental influences. The mind is the first fact and must lead, the body is secondary and must follow. Trouble begins when this order is reversed and the body is allowed to dominate. But with a sound body, perfectly obedient to the laws of nature and subject to a mind free and independent, one might naturally expect perfection of health, which means, of course, the absence of disease, and were it not for disease there would be no need of medicines.

1. Prominent among the causes of disease is that negative one, lack of resistance, and modern research teaches no more important lesson than that disease of any sort, germ diseases like others, occurs in the same measure as this resistance is lacking. It is well known that this lack is often caused primarily by mental depression and its consequent physical depression, the one being an exact measure of the other; and the general health being thus reduced, it is perfectly natural for the most vulnerable part (the point of least resistance) to show the first signs of failure. It is the weakest link which gives way first in a chain subjected to general strain. And so with the organs of the body—which for the purpose of comparison may be considered as links of a chain—it is the weakest which first shows signs of disorder during any stress on the general system. In short, mental depression causes physical depression, and physical depression means lack of natural resisting power, or *susceptibility*. So mental depression is remotely the cause and equivalent of susceptibility. The first cause, the cause of causes, is thus seen to be mental in these cases.

2. The effect of the mind on the body may be seen to good advantage in the delicate sensitiveness of the individual constituent cells forming the different organs, for we know that whatever affects the single cell may affect the whole organ; that is, the organ through the cell, not the cell through the organ. No one can read Prof. Mosso's book on "Fear" without arriving at the conviction that at least this emotion (fear) produces changes in the circulation and cell-nutrition that are most remarkable. A moment's reflection will make it clear how fine and delicate the influences might be, mental or physical, to operate for or against this minute organism. Bathed as it is by the fluids of the body (itself the product of these same cells), it depends on the normal condition of these same fluids for its maintenance, growth and healthy action. Many and various are the delicate causes, in the mental sphere, of disturbed relations of these parts, which disturbance means want of harmony, and want of harmony means more or less dis-ease. And these minute organisms, according to Mosso, are affected alike by mental and by physical means.

3. An important group of mental cases are those in which certain emotions produce in the system substances of apparently poisonous nature. For example, a nursing mother, affected by violent anger, may develop in the milk secretion poisons which cause vomiting, convulsions, or actual death of the child. Medical literature gives many instances of this sort. If the milk secretion is thus affected by emotion, is it not a legitimate and necessary inference that other secretions (perhaps also excretions) are similarly affected? This has been

shown by actual experiment. This being true, would not careful examination show that different organs produce different baneful substances, according to the violence of the emotion, its character, duration, etc., substances which might act injuriously on the person secreting them, causing disorder and finally disease? The inference is wholly logical and legitimate. In such cases it is evident that only mental treatment is indicated.

4. A fourth class of cases is seen in the functional disorders of different organs caused by depressing emotions, the more violent the emotion the more acute and severe the disorder. Among these emotions may be mentioned grief, fear, fright, anger, hatred, jealousy, envy, etc. How often, for example, is loss of appetite caused by violent emotion, or impairment of digestion, nausea, vomiting, perhaps diarrhea. Insomnia is a frequent result; the hair may be rendered harsh and dry, perhaps turned gray; the perspiration increased or diminished, or the saliva affected in the same way; the temperature raised (fever) or lowered (chill); headache is a common consequence; there may be palpitation of the heart, difficult breathing, etc.; the urinary secretion is often affected, and so forth. If such emotions are allowed to control the mind indefinitely, these disorders tend to become fixed, and finally result in actual disease. These emotions, with the consequent physical disorder, are so frequent and familiar illustrations of the effect of the mind on the body that it is remarkable that the far-reaching significance and the necessary inferences have not been more generally recognized, especially by medical men, who appear to have almost wholly neglected them. For it is readily seen that chronic disease may be due, and due only, to long-continued mental depression of this sort. One needs only to look about among acquaintances to discover many such cases. The patient, and too often the physician, failing to see any connection between the immaterial cause and the material effect, ascribe the disorder to something else, and therefore what might be got at and perhaps easily removed is allowed to remain, a monument to the ignorance and consequent inadequate treatment of the medical man. Very many ailments, often of chronic character, belong to this class.

5. A fifth cause is more profound and one that affects the moral nature or the character itself, and though it may seem to some that there is no relation between moral soundness and physical soundness, it is the verdict of the ages that there is an unalterably fixed relation. But the age in which we live is given up to materialism, a devotion to material things and interests, the neglect of spiritual for physical needs and considerations. The effect of moral character on the physical health must be looked for, however, only among such as would be guided by conscience, and therefore with the idealists. To define the limits of this influence is not an easy task, and I cannot claim the qualifications necessary to do more than point out what seem the most conspicuous facts.

The soul being the first and most important fact, the care of it rightly demands one's first attention and best efforts. This is the theory, to which there are very few dissenting voices among thoughtful and well-informed men anywhere. But conviction is worthless till it converts itself into conduct and character. If a man is convinced that the soul is supreme and should govern the body and the senses, and not be governed by them, may we not naturally expect disorder and disaster first, last, middle, and all the time, when the poor soul is driven into a corner, dethroned and silenced? The question naturally occurs, is not man to a large extent misdirecting his energies and striving day and night continually for that which profiteth not? Is it not a fundamental mistake to ignore the injunction of the world's greatest Teacher—"Seek ye first the Kingdom of God, and all other things shall be added?" If man is not heeding this grand injunction, and still feels the imperative necessity of doing so, is not here a source of eternal discord and dis-ease? Is he not consciously working at cross purposes by thus yielding obedience to the senses and silencing the voice of conscience? "The ingenuity of man has always been dedicated to the solution of one problem—how to detach the sensual sweet from the moral sweet, the sensual fair from the moral fair—to get a *one end* without the *other end*. The soul says, eat; the body would feast. The soul says, the man and woman shall be one flesh and one soul; the body would join the flesh only. The soul

strives amain to live and work through all things. It would be the only fact. All things shall be added unto it—power, pleasure, knowledge, beauty.”

It seems to me that the pith and essence of the Christian science doctrine is its idealism; if one word may be used to define it. To be sure, it is a blind and ill-advised attempt to realize the ideal. But it seeks to enthrone the soul, to make it and not the body the final arbiter. And the man who has abandoned himself to this guide, and feels himself in the grip of this imminent and invincible force, has faith in it and trusts himself to it, bending himself in loving obedience to all its dictates, is in possession of, or is possessed by, a power for good that is great beyond comparison. Above all, is it a source of self-reliance and self-confidence, and consequently of health, strength, and vigor almost without limit. It acquaints man with himself and his own resources, serves to put him on his own feet, allies him with nature which, by keeping its laws, he is able to command. Everyone knows the great value of this self-confidence—coming from an infinite faith and a perfect trust in this indwelling force—which goes far toward making the man invincible.

It is not necessary here to refer to the many erroneous beliefs and the consequent absurd practices of our Christian science friends, but aside from these and back of them is this residuum of truth which is sufficient to account for the healing of disease done by them—and to them miraculous and positive proof, as they claim, of the general correctness of their theories; but to one acquainted with psychology, neither the one nor the other. Both Christian science and mind cure (which, unlike Christian science, is, at its best, thoroughly rational and scientific) have too many apologists of the unscientific sort, men who evidently are not used to dealing with ideas (except in bad English), who have, most unfortunately, but one idea, and who, therefore, say many things that are both untrue and absurd. But they have had a vision—have seen a fact in Nature—but as they do not understand it, they, of course, cannot rationally explain it. Hence so many extravagant claims and so many statements practically false, though made with the firm belief that they are true. What these men need is not ridicule, but information, and other ideas to balance and correct the single idea which now so overwhelms them. Not being able to classify their fact, they must submit to the mortification of being classified by it. But some allowance should be made for them. They have seen a truth at first hand, and its significance they cannot measure, so they claim everything for it, as it is easier to believe than to judge. Inclined to mysticism, they believe because they cannot understand. The greater the mystery the stronger the attraction.

On the Delphian temple were inscribed the words, “Know thyself,” and no other knowledge is comparable with this. But in these days, who teaches man this knowledge? Surely not the schools, nor the church. But he learns it, if he learns at all, in God's dear school of experience, and too often learns so late in life that he can put his knowledge to little use in the betterment of himself or of others.

Finally, mental science, in its best sense, undertakes no less a task than the regeneration of the soul, for this is the necessary fundamental work. It aims to teach the man how to think, and, therefore, how to act—in short—to know himself. It braces the will (the man), teaches self-reliance and self-confidence; endeavors to unmask adversity, and to show that it is really but the prosperity of the great; that calamities are but divine instruments of training; that the ills of life may be, and should be, our schoolmasters, that they are disciplinary and educational; that depressing emotions, such as anger, hatred, envy, etc., are not to be indulged in, for the reason that they are even more harmful, both in mind and body, to the one influenced by them than to the one they are aimed against. It is a rational and logical system of getting at the springs of action, and, therefore, whether in disorder of the mind or of the body, it seeks the cause—the first cause—and when the cause is removed the effect ceases of itself—the only reasonable mode of curing anything. It not only aims to put the man on his own feet, give him possession of himself, and acquaint him with his own sufficient resources, but also to show him how he may be able to cope with the various requirements of life. It teaches

that “man is a born subject, and the service of God is perfect liberty;” that character counts, not wealth nor station; that the soul is supreme, and, therefore, in matters of doubt is the sole arbiter.

THE WORLD'S LATEST LITERATURE

Journal of the American Medical Association.

March 5, 1904. [Vol. XLII, No. 10.]

1. The Present Status of the Medical Expert. ALGERNON T. BRISTOW.
2. Chronic Adhesive Sclerosing Peritonitis, or Plastic Peritoneal Sclerosis. HORACE G. WETHERILL.
3. A Study of Gout. JAMES D. MORGAN.
4. A Study of a Case of Green Urine, Resulting from the Administration of Methylene-blue in a Proprietary Remedy. JAMES M. COOPER.
5. A Report of Ten Cases of Pneumothorax Occurring in Pulmonary Tuberculosis. J. W. TRASK.
6. Headache from Nonsuppurative Inflammation of the Accessory Sinuses of the Nose. CHARLES M. ROBERTSON.
7. Hospital Experience Necessary for Licensure: A Suggestion in Medical Education. LAWRENCE E. HOLMES.
8. The Plastic Surgery in the University Maternity for the Year 1903. BARTON COOKE HIRST.

2.—Chronic Adhesive Sclerosing Peritonitis.—H. G. Wetherill finds that this disease has escaped recognition in most American textbooks. It may occur at one or many points in the peritoneal cavity as a consequence of chronic inflammation, the thickening finally leading to shrinking. Many cases have no acute stage, and are without definite cause for onset. Chronic constipation often results from the adhesions. It is not primarily a peritonitis, but a distinct affection of the sub-peritoneal and visceral connective tissue, the feature of adhesive peritonitis supervening as a result of traumatism, operation, or transmigration of intestinal bacteria. Might it not better be called plastic peritoneal sclerosis? He reports a case, the points of interest being rareness, failure to generally recognize it, its exhibition of the pathognomonic sign, inability to unite a shrinking peritoneum when once divided during operation, the chronicity of the case, the importance of covering all denuded surfaces to prevent adhesions, the characteristic hyperplasia, the shrinking, the possible significance of a similar process in the skin coincident with unaccounted for gastrointestinal symptoms, the diagnostic value of this syndrome, the danger of serious sequels incident to surgical treatment. [H.M.]

3.—Gout.—J. D. Morgan illustrates his articles with cuts, including radiographs of gouty and other conditions of the joints, showing the deposits in gout and the destruction of the bony tissue in arthritis deformans. In chronic rheumatism it is often astonishing how little the joint may be altered. He discusses the difficulty of distinguishing clinically at times between rheumatism and gout. [H.M.]

4.—Green Urine.—J. M. Cooper reviews the literature of the subject, which is scanty in America, and details the various tests applied to the urine in the case reported, these showing that the quack pills which the patient had taken contained an impure preparation of methylene-blue, the impurities probably being small amounts of basic anilin greens, either malachite or helvetia green. Practically all cases of blue or green urine reported have been due to some anilin dye. Urine is frequently green instead of blue after taking methylene-blue, especially that first voided. In this case the green may have been due to modification of a faint blue by the intense yellow of the urine noted when the pigment was removed. [H.M.]

5.—Pneumothorax in Pulmonary Tuberculosis.—J. W. Trask reports 10 cases, 5 of which were approaching the period when their tuberculosis could be considered as arrested. With 2 or 3 exceptions the accident occurred when the patient was not exerting himself, 5 attacks coming on in the night. The extent depended on the adhesions, perforations occurring where these were young and friable. Eight cases had fluid in the cavity. The symptoms of onset were intense pain in the affected side, dyspnea, distress, cyanosis, and rapid pulse. In one case there was no pain. The patient lay on the sound side till the pain subsided, and then on the affected side. The symptoms were as severe in the partial as the total cases. Pneumothorax would seem to be more common at Ft. Stanton than elsewhere, and the prognosis less hopeful, 8 of the 10

patients dying. This may possibly be due to the altitude, 8,150 feet. [H.M.]

6.—Headache from Inflammation of the Accessory Sinuses.—C. M. Robertson thinks the pain is produced by diminution of pressure, the oxygen being absorbed after closure of the opening by the swollen mucous membrane. He relieves the condition by applications of cocaine, adrenalin, etc., to the turbinates. [H.M.]

7.—Hospital Experience Necessary for Licensure.—L. E. Holmes thinks present methods for raising the standard inadequate. It will be many years before any but the best schools will require a college degree. He suggests that State boards require at least one year's hospital work as interne before a license is granted. That there are not enough hospitals for each graduate should result in cutting down the number of students now far in excess of the demand. Such a requirement is imposed in other countries. [H.M.]

8.—Plastic Surgery in the University Maternity.—B. C. Hirst for several years has repaired all the accidents to the parturient canal during the puerperium. The results have been good in every case. An operation on the cervix before the fifth day is often followed by infection of the endometrium. At the end of a week this is not the case. Operation is under anesthesia. The cervix has been repaired in 53 cases and the anterior vaginal wall in 42 cases during the year. Why should any woman be condemned to years of disability and invalidism as the result of childbirth, and finally be subjected to a secondary operation when she could be restored to a perfect physical condition during the lying-in period. [H.M.]

Boston Medical and Surgical Journal.

February 18, 1904. [Vol. CL, No. 7.]

1. Slipping or Recurrent Dislocation of the Patella; with the Report of Eleven Cases. JOEL E. GOLDTHWAIT.
2. Scientific Aspects of Moderate Drinking. FRANCIS GANO BENEDICT.
3. The Use of Obstetric Forceps. WARREN R. GILMAN.

1.—Slipping or Recurrent Dislocation of the Patella.—J. E. Goldthwait says this condition is seen almost entirely in girls or women, being due mainly to the angular pull of the quadriceps extensor muscle and often associated with flat-foot. The tendency to recurrence is increased by an abnormally long patellar tendon, knock-knee or unnatural development. In an operation the chief object is the straightening of the line of the pull of the anterior thigh muscles. This is best accomplished by transplanting the outer half of the patella tendon so that it is attached well to the inside of the tubercle of the tibia. If the tendon be too long it can be shortened. The relaxed capsule is a result of the mechanical pull and can be ignored. Eleven cases are reported and of them 7 were operated upon. Of the operated cases, 4 had the outer half of the patella tendon, and one had the entire tendon transplanted to the inside, and as 3 had both knees treated, there were 8 operations, with normally strong joints in 7, the ultimate result in the eighth being uncertain, as sufficient time has not elapsed since the operation. [A.B.C.]

2.—Moderate Drinking.—F. G. Benedict discusses the vagueness of the boundary-line between moderation and excess, and shows that neither Anstie's physiologic limit, $1\frac{1}{2}$ ounces, nor Abel's, which is about half the former are applicable to all individuals. Statements of persons habitually using alcohol as to its beneficial or deleterious effects are unreliable. Medical men are changing their views radically regarding the use of alcohol as a tonic, digestant, heart stimulant, etc. Whatever differences of opinions exist among others, the life insurance companies are agreed that drinkers belong in the class of hazardous risks. In these companies we have the best separation of heavy drinkers from moderate drinkers, and consequently can make more exact comparison between the latter and total abstainers. In one of the largest English mutual companies the average ratio of actual to expected deaths in the total abstinence section has been 24.7% less than that in the general section. The bonus was correspondingly greater. Dr. McClintock, in this country, has found a difference of 18%. These percentages are too large to be wholly attributed to habits other than that relating to the use of alcohol. The

proved effects of small doses in decreasing intellectual activity should be clearly stated to the general public, for they are important in determining a man's efficiency. In typesetting a difference of 15% has been demonstrated. The greater efficiency of American over English workmen is due largely to differences in drink habits. A railroad president writes: "All large employers establish rules which make it practically impossible for an employe who uses liquor to remain in the service." That there is 1 drunkard among every 74 males shows the danger of habit formation. The average young man, using alcohol, jeopardizes his chances of success through diminution of mental and muscular power, and antagonizing the prejudices of his employer. [H.M.]

3.—Use of Obstetric Forceps.—W. R. Gilman says the forceps being applied, traction should be made forward until the occiput clears the symphysis; then the handles are raised and the head extended over the perineum. The perineum should be dilated slowly by intermittent tractions, the head being allowed to recede between them. It is his custom to remove the forceps when the head has thoroughly dilated the perineum. With the patient on her left side, the thumb behind the anus pushes the head forward over the perineum, and delivery of the face is accomplished as in normal labor. The high forceps operation is very difficult, and, in the hands of any but the most experienced, dangerous for both mother and child. When the head floats, or the largest diameter of the head does not come through the superior strait, he much prefers version to forceps, and with the average practitioner the results are much better. If the membranes are ruptured, however, version is dangerous, if not impossible. When the head has engaged, the forceps may be applied and, if impossible to place them in perfect position, grasp the head obliquely, one blade over the temple and the other over the posterior parietal bone. As the head descends, change their position to a better one on the sides of the head. [W.K.]

Medical Record.

1. The Treatment of Gunshot Wounds by British Surgeons during the War of the Revolution, 1775-1783. STEPHEN SMITH.
2. The Rationale of the Natural Arrest of Tuberculosis; a Study Explaining the Effect of Sea Voyages, Outdoor Life, Etc., on the Disease, with Suggestions as to Ideal Treatment. W. B. McLAUGHLIN.
3. Running Ear. A. C. BARDES.
4. Neuralgia Due to Dental Irritation. WILLIAM J. LEDERER.
5. The Physiology of Hunger. AXEL EMIL GIBSON.

1.—Treatment of Gunshot Wounds During the Revolutionary War.—Stephen Smith, in his article, quotes largely from H. St. John Neale, surgeon in the British Army during the Revolutionary war in America. The numerous quotations, together with comments thereon, make up an interesting article. For instance, Neale asserts that he instructed all of his noncommissioned officers in the application of the tourniquet, and each one of such officers carried a tourniquet constantly with him. Thus it appears that an elementary form of first aid to the injured was instituted at this early date. He held that gunshot wounds at that time healed kindly, but there were 4 indications to be fulfilled in order for recovery to take place. He lays much stress upon dilation of the wound in the treatment, and held that removal of the ball should not be attempted if it was attended with much laceration of the tissues. In this he asserts that he differed from most of his fellow surgeons. He asserts: "Every contusion of the skull requires the trephine, because it must be done sooner or later with disaster to the dura mater." He held that wounds of the spinal cord, stomach, intestines, pancreas, and liver were almost universally fatal, though the wounds of the lung, in many cases, were recovered from. Opium and Peruvian bark he mentions as among the definite remedies to be administered in the internal treatment of gunshot wounds. [A.B.C.]

2.—Rationale of the Arrest of Tuberculosis.—W. B. McLaughlin says that if we assume that bacilli are finally destroyed by the formation of an antitoxin within the tubercle, we also assume the impossibility of reaching them in their walled-off condition by the injection of an antitoxin into the circulation. The rapidity with which the germ is walled off is

directly proportionate to the vascularity of the tissue involved. The chronicity of the disease in the lung is due to admixture with pus cocci and constant reinfection. Success in treatment depends on the degree of completeness in preventing reinfection. Upon this depends the value of climate and mode of life. More people have tuberculous nodules in their lungs without symptoms than the number of those who die of tuberculosis. What takes place in sanatoriums is the conversion of mixed infection into pure tuberculosis, or the conversion of mixed infection into one of less virulence, consequent on less frequent reinfection; or on reinfection with attenuated pus organisms. If a patient with chronic ulcerative tuberculosis is kept in sterile air and his person as aseptic as possible, his ulcerative tuberculosis will be converted into a pure tuberculosis, or what is known as latent tuberculosis. Autopsies teach us that only 40% of latent tuberculosis cases become active. Thus we can logically expect 6 out of every 10 cases treated, to remain well, and 4 to become reinfected and return for another period of treatment. [H.M.]

3.—Running Ear.—A. C. Bardes asserts that a discharging ear is nearly always the sequel of an acute otitis media and the fact that it becomes chronic is proof of the lack of proper attention in the acute stage. In treating this condition the relation of the internal ear to the pharynx, mouth and nasal cavities must be kept constantly in mind. Formerly this disease was regarded too little and even today it does not receive proper attention; 3% of all persons suffering from a discharging ear die from the results of such aural complication. A suppurating ear may at any time burst into renewed activity and become a dangerous or even fatal condition. In the early stages of the suppurating otitis merely the connective tissues of the middle-ear are involved, but later the bony portion becomes involved and the disease often extends to the antrum and mastoid cells. Multiple perforations in the ear drum are indicative of tuberculosis; perforation high in the drum indicates increase of the ossicles. In the treatment the membrane should be incised freely and thorough drainage established. The irrigations which he has found of most value are: A weak solution of silver nitrate, zinc chlorid, carbolic acid, formalin, tincture of iodine and mercuric chlorid. [A.B.C.]

4.—Neuralgia Due to Dental Irritation.—William J. Lederer says the causes of dental neuralgia are many, but it has predisposing factors. Anything that lowers the resistance of the system will modify the conditions resulting from dental irritation, and anemia, syphilis, gout, and rheumatism predispose to neuralgia. The exciting causes are acute and chronic periodontitis, acute and chronic pulpitis, sensitive dentine, caries, pyorrhea alveolaris, foreign bodies in the gum, alveoli, or pulp chamber, and atrophy of the gum. Prognosis is favorable unless it is associated with other conditions, as malaria or syphilis, when it assumes the infective type. The acute diathesis in malaria must be looked for and treated in many of these cases. The exciting cause must be removed in all cases, constitutional treatment, when necessary, must be instituted, and mild cathartics given. Dover's powder may be useful, likewise codein, the various antipyretics, and quinin. Atrophy of the gums following removal of the teeth may be a cause of neuralgia. Impacted teeth are sometimes a cause of dental neuralgia, and these must be removed. The author has secured good results in the treatment of these neuralgias by the administration of quinin, iron, and arsenic combined, and at times nux vomica. [A.B.C.]

5.—Physiology of Hunger.—A. E. Gibson defines normal hunger as a sensation arising in consciousness whenever the balance between waste and repair is broken. It is a nervous act. When the stomach empties itself its motion ceases and the nerve terminations in its walls stimulated by the accumulated secretions of the glands, send irritations to the spinal cord and brain, which are interpreted in terms of hunger varying in intensity with the intensity of the conscious response to the stimulation. The sensation can be modified by mental effort. By refusing to entertain thoughts and images of food the gastric secretion will receive no stimulation and hunger be kept in abeyance. Demented and hysteric persons whose minds are busy with other subjective images may starve for weeks without making known any sensation of hunger. The case of

Antonio Viterbi, who chose starvation in preference to hanging for a political offense, also illustrates the power of subjective states in abolishing hunger. On the other hand, persons forced into starvation and fascinated with the imagery of a riotous appetite suffer indescribably and generally lose their reason before they lose their lives. There is a power in every individual enabling him to subdue morbid craving for food and drink. The secret of breaking a habit or passion lies in keeping the mind off the enticing subject. [H.M.]

6. The Use of Formaldehyd as a Preservative in Urine. FRANK W. KENNEY.
7. The Comparative Digestibility of Raw, Pasteurized, and Sterilized Milk. T. M. PRICE.

3.—Thrombosis of the Cavernous Sinus.—Henry Roth discusses this condition and reports 3 cases. In the first case, a carious tooth in the upper jaw was undoubtedly the starting point for a fatal infection. In the second case, the thrombosis could be traced back to a furuncle on the nose, and in the third case, a furuncle on the upper lip, which was incised early, must be assumed as the point from which the infection spread along the venous blood-current up to the cavernous sinus. Cerebral symptoms were marked in all, but of greatest diagnostic value were the eye symptoms. The writer considers thrombosis of the cavernous sinus a very grave and fatal disease, which is usually secondary to some infection about the face or mouth. The causative agent, in the great majority of cases is *Staphylococcus aureus* or *albus* and *Streptococcus*. The infective process may spread by contiguity of tissues, but, in most instances, it is by continuity of the inner coats of the veins or the neighboring sinuses. [C.A.O.]

6.—Formaldehyd and Urine.—F.W. Kenney, after a careful investigation of the subject, says that formaldehyd, as an artificial ingredient of the urine, will lead to deceptive results in urinalysis by (1) making the urine appear albuminous when it is negative; (2) not giving a typical reaction when albumin is present. He says that the reliability of Introna's test, namely, the use of formaldehyd in albuminous urine as a reagent, is to be questioned, inasmuch as the effect of formaldehyd on negative urine is the same, though to a more marked degree, as that on albumin in solution, the difference in the color and density of the precipitate being, in his opinion, immaterial. He believes that as a factor in the production of a possible pseudoalbuminuria the therapeutic use of urotropin is a subject well worthy of extended observation and study. [C.A.O.]

6. Suture of the Omentum to the Parietal Peritoneum (Epiploexy) for Ascites. JOSEPH H. BRANHAM.

1.—Pathologic Anatomy of Shiga Bacillus Infection of the Intestines in Infants.—John Howland enumerates the pathologic findings of Strong and Musgrave, Harris, Flexner, and others, and reports certain cases coming under his own observation. These are divided into 2 groups; one group comprising 5 cases, each representing the most severe changes met with and are similar to those found by Flexner and Strong. These are reported in some detail. The other group comprises 4 cases presenting a different picture. In these the mucous membrane in both large and small intestines was in a good

state of preservation, but the lymphoid elements had suffered to a marked degree. Characteristic cases are recited in detail. In conclusion he says: "If we endeavor to sum up the case as is here made out for the Shiga bacillus we shall have to say that there are comprised under the lesions associated with it, all grades and types of diarrheal disease as distinguished by clinical symptoms and pathologic findings and that it can be affirmed that no particular type is distinct from the others by a special etiologic region." [A.B.C.]

2.—Utilization of the Lower Lip in Rhinoplasty.—Carl Beck reports that a woman of 55 had suffered from epithelioma of the nose, which organ having been largely destroyed, the Indian method of rhinoplasty had been performed by swinging a triangular flap of skin from the forehead down over the nose. This resulted in a fair restoration, but a recurrence of the epithelioma again destroyed the organ. The author then operated by the Italian method, making a new nose from the tissues of the left arm. Recurrence again destroyed the improvised nasal member; again an operation was undertaken, which is herewith reported. After outlining a triangular flap, the lower lip was divided into its whole thickness from an inch from the left angle of the mouth downward to the chin. The flap-formation was finished by dissecting upward to the angle of the mouth, stopping a half inch below, in order to obtain a suitable bridge. The tip of the triangular flap was then turned around and sewed to the margins of the nasal defect, after extensive excision of the epitheliomatous area. The upper portion of the flap could be well approximated and fastened with silk sutures. A part of the flap had to be left free, as is shown by the black sphere overlying the upper lip. The results were good. [A.B.C.]

4.—Traumatic Pyeloparanephric Cyst.—B. B. Gallaudet reports that a youth of 12 was struck in the abdomen, which necessitated his being confined to bed for several days. After this his health was good for some 2 years, except for more or less continuous pain in the right side of the abdomen. He then fell, striking the abdomen with considerable force, for which he was again confined to his bed for 4 or 5 days with nausea, vomiting, and bloody urine. A month later the pain became intense, accompanied by abdominal distention; laparotomy was performed, and a quart of bloody fluid with blood clots was evacuated; the sac from which this came appeared to be connected with the kidney. The wound healed, with the exception of a sinus, from which urine was discharging. After several months there appeared attacks consisting of high temperature, delirium, and cessation of urinary flow from the sinus. Operation was again performed, and a pyeloparanephric cyst found, to which the old sinus led. Nephrectomy was performed, on account of the diseased condition of the kidney. Recovery was uneventful. He assumes (1) That the first traumatism ruptured the pelvis of the kidney and also caused a hematuria both within the pelvic cavity and in the paranephric tissue; (2) that the blood was gradually absorbed, and the thickened capsule (extrapelvic portion) of connective tissue was formed from the paranephric tissue; (3) that the second traumatism caused a fresh hematoma. [A.B.C.]

5.—Ergot in Drug Habit Cases.—A. T. Livingston does not regard the drug habitus as the subject of a specific disease with its logical sequence, irresponsibility. With forced deprivation there is intense agitation of the cerebrospinal system, with vasomotor paralysis and resultant intense hyperemia and sensation of heat to the hand. Many of the cases are due to unwise use of the narcotics by medical men, when ergot would have more surely relieved the pain, nervousness, and sleeplessness. There are several methods by which equilibrium of the circulation may be secured including cold applications, galvanization, dry cupping over the spine, massage, and hypodermics of ergot, the latter being preferred by the writer. Its most pronounced action is on such areas as are relaxed. Livingston advises immediate discontinuance of the narcotic thus demonstrating to the subject that the drug is not necessary to him, at the same time anticipating the violent reactionary stage by administering ergot from the start, with a mercurial and saline purge, and afterward easily digested nourishment every 3 hours. [H.M.]

6.—Epiptoxy for Ascites of the Liver.—Joseph H. Branham reports that a woman of 60, who had used beer freely

for a number of years, complained of poor health, abdominal distention, and indigestion. The limbs were edematous and the skin was of a yellowish muddy hue; she had never been tapped. Laparotomy was performed, 6½ gallons of slightly blood-stained fluid evacuated, and the middle portion of the omentum sutured to the abdominal wall on each side of the incision; drainage being inserted, much fluid came away. Subsequently the wound healed, and for 6 months after the operation her health was better than it had been for years, the ascites and edematous condition of the limbs having disappeared. After this time there was pleural effusion, the chest was tapped, 5 quarts of bloody serum evacuated. The case reported shows several points of especial interest: 1. The presence of the vascular adhesion showing the effort of nature to form collateral circulation. 2. The subsequent occurrence of pleural effusion with no ascites points strongly to good collateral circulation for the portal system. 3. The marked improvement in the patient's general condition shows better functioning of the liver and intestinal organs after the operation. [A.B.C.]

CLINICAL MEDICINE

DAVID RIESMAN

A. O. J. KELLY

EDITORIAL COMMENT

Digitalis: Its Nomenclature.—Digitalis still remains with us; one of the very few weapons of our therapeutic armamentarium, whose properties and powers have borne without flinching or paling the searchlight cross examination of over a century. It has been subjected to the severest scrutiny throughout the whole of the nineteenth century, the most scientific, the most skeptical, and the most progressive of all the epochs of human history. Yet it has every time left the court without a stain on its character. Whenever mischief had occurred in connection with its use, the fault was not with the weapon, but with the misguiding hand. Digitalis is one of the very few powerful therapeutic agents obtained from the vegetable kingdom, of which no definite lore or knowledge has descended to us from classic writers. Among the authorities of the period of the renaissance of botany, Columna indeed would identify digitalis with the *Ephemerum* of Dioscorides; and Dalecampius regards it as the *Calathiana viola* of the elder Pliny. But there is no conclusive proof. Its present appellation of *Digitalis* is by no means of classic origin or date. It was conferred in the sixteenth century by Leonard Fuchs, one of the fathers of modern scientific botany, whose name is embalmed for all time in that of the botanic genus *Fuchsia*. It was, of course, suggested by the resemblance of the flower to the finger of a glove. To a similar origin was due the German (popular) appellations of *Fingerhut* and *Fingerkraut*; also the French ones of *gant de Notre-Dame* and *Doigtier*, and the Dutch of *Vingercruiddt*. It is of some interest to note, for purpose of correction, the mistake which is still made by the great majority of uninquiring readers—even many medical ones—that the English name of "*Foxglove*" had a similar origin. This latter appellation is really an altered form of the Anglosaxon word *Foxesglew*—fox's music—and is an allusion to an antique musical instrument, which consisted of a bell attached to the end of a support curved in form of a bow.

The Older Therapeutics of Digitalis.—The genuine professional recognition of the therapeutic value of digitalis is essentially modern. Its use—probably extensive—in classic and medieval times appears to have been among the uneducated, and after unskilled advice. We are told by the great London herbal authority, John Parkinson (of *Paradisus-in-Sole* fame), in 1640, of the known "vertues" of digitalis at that date:

The Italians have an usual proverbe with them concerning this herbe, called by them *Aralda* which is *Aralda*, *tutte piaghe salda*: *Aralda* salveth all sores: for they use it familiarly to heale any fresh or greene wound or cut, the leaves

being but bruised and bound too, and sometimes also they use the juice in old sores to cleanse them, dry up their moisture, and heal them the more speedily, which it performeth by the bitter quality therein whereby it is found to be heating and drying, and cleansing withal; so that whensoever there is neede of a rarefying, or extenuating of thicke tough flegme and viscous humours troubling the chest or stomacke; the decoction or juice hereof made up with some Sugar or honey is available, as also to cleanse and purge the body both upwards and downwards sometimes, of tough flegme, and clammy humours, and to open the obstructions of the Liver and Spleene; and yet notwithstanding that these qualities are found to be in it, there are but few Physicians in our times that put it to these uses, but is in a manner wholly neglected: It hath beene found by late experience to be available for the King's Evil, the herbe bruised and applied to the place, or the juice made up into an ointment and used thereon: And it hath beene of later experience found also to be effectual against the Falling sickness, that divers have been cured thereby; for after the taking of the decoction of two handfulls thereof, with foure ounces of *Polli-pody*, of the oake bruised made in Ale, they that have beene troubled with that disease 26 yeares, and have fallen once in a weeke or two or three times in a moneth, have not fallen once in 14 or 15 moneths, that is untill the writing hereof, which I thinke may be said to be an absolute cure, not to be presumed that after so long stay it should returne againe.

The latter therapeutic result—of the use of a fresh decoction of digitalis leaves—does not appear to be generally known; although we have heard of its being recently tried with good effect.

General Effects of Digitalis on the Circulation.

—The development of the modern scientific therapeutics of digitalis dates from 1775—and from the city of Birmingham, the English “midland capital.” It was then and there that Withering, the friend of the famous nosologist Cullen, published his epoch-making brochure on this plant, which he called the *opium of the heart*—on account of its sedative effects on that organ, and the consequent slowing and steadying of the pulse. He also pointed out its “hydragogue” properties. Soon after this date, Solerne published the results of his experiments with digitalis on the circulation in the turkey. Schieman, in 1786, gave to the world the results of his more elaborate experiments on the dog and cat. Both those observers reported slowing of the cardiac pulsations. Beddoes, in 1801, announced that digitalis produced an increase of the blood-pressure. This effect he attributed to augmentation of the contractility of organic muscular fibers throughout the vascular system. In the same year, Kinglake sustained the thesis that digitalis acts simultaneously on the heart and the arteries. Curiously enough, even till after this date, the sedative theory of Withering was the only one generally recognized in France, owing to the great authority of Bouillaud, by whom it was introduced to the medical public of that country. Nevertheless, Beau, without appearing to be acquainted with the above history, and without having had recourse to physiologic experimentation, had already in testimony of the results of his own clinical observation, given to digitalis the appellation of “*quinin of the heart*” (*quinquina du cœur*). At the present day—after the lapse of another century, and that one more scientific and experimental than the sum total of its predecessors—we find those three (above mentioned) cardinal facts established, beyond fear of contradiction, in connection with the ingestion of digitalis: 1. Slowing of cardiac movement. 2. Increase of contractile energy of cardiac muscle. 3. Elevation of arterial pressure. But, as would be anticipated by all readers who have had a certain amount of experience of human nature in general, and of its developments in connection with physiologic investigation in particular, the theoretic explanations of these phenomena which have been hitherto advanced, still continue to display marked degrees of divergence.

The Potent Chemic Principles of Digitalis.—

Like most other plants which exert a very powerful influence upon animal life when taken into the system, digitalis owes its peculiar powers—for good and for evil—to the presence of certain definite chemic com-

pounds, which can be isolated therefrom in the crystalline form. The chemic active principle first obtained from this plant was, according to the usual form of nomenclature of organic chemistry, named *digitalin*, by its discoverers MM. Homolle and Quévenne. It came to be known as “amorphous” digitalin soon after; when M. Nativelle succeeded in separating a crystalline compound, which was regarded by its discoverer as “true” digitalin—and the real active principle of the amorphous digitalin itself. This view seemed to be borne out by the fact that the strength of the preparations of the amorphous digitalin were hopelessly unreliable; and that those of the new crystalline substance were fairly trustworthy. But, although much more uniform than the amorphous, it was soon discovered that the digitalin of Nativelle offered no safe standard. The more elaborate researches of the German pharmacologist, Schmiedeberg, soon afterward brought our knowledge of the organic chemic principles of the digitalis plant to a state of approximate accuracy. Of these there have been separated and studied: *Digitalin*: A granular, if not satisfactorily crystallizable glucosid, which possesses in high degree the characteristic action of digitalis. So much so that Kiliani and some others would name it *digitalinum verum*, and regard it as the most effective method of administering digitalis. It has all the characteristic influence on the heart, and its effects are noncumulative. *Digitalein*: An amorphous glucosid, probably a mixture. Its action on the heart is noncumulative; and it causes no local irritation when injected subcutaneously. *Digitoxin*: Regarded by some as an alkaloid—is certainly not a glucosid. It is the most active (toxic) and dangerous of all the constituents. Its effects are cumulative, although of uncertain degree. *Digitonin*: A glucosid constituent, and forming the larger part of the total constituents of this class. Has an influence on the inhibitory nervous mechanism antagonistic to that of digitalis. *Digitin*: A physiologically inert crystalline principle.

Effects of Digitalis on the Cardiovascular System.—Experimental observers have described 3 degrees of the effects of administration of digitalis—according to the dose; and 2, 3, or 4 periods of their manifestation. The 3 degrees are: Pulse slow and regular; pulse quickened; pulse slow and irregular. The safely effective therapeutic dose produces effects not surpassing the first of these degrees. In such cases 2 periods are definable: The period of action; the period of gradual return to the normal state. A dose somewhat larger realizes 3 periods: Pulse slow; pulse quickened; return to the normal state. The administration of an actually toxic dose furnishes 4 periods: Pulse slow; pulse quickened; pulse slow and irregular, followed by cessation of pulse more or less prolonged; death, or return to the normal state. According to the German authority, Schmiedeberg, the first effect of digitalis is to increase the elasticity of the heart—what is called by other observers the “activity of the diastole.” From this results the negative intraventricular pressure pointed out by Goltz and Gaule. This increase of elasticity produces the augmentation of the volume of the pulse which precedes the elevation of the blood-pressure, independently of the latter. Kaufmann has studied in succession the action on the heart, and on the arterial system. With regard to the first there occurs at the outset a fall in the number of beats per minute. The cause is stimulation of the (inhibitory) pneumogastric nerve at its bulbar origin, and at its cardiac terminations. It is not a bulbar stimulation only, as Traube thought, for after preliminary section of the vagus the slowing effect is sometimes observable. Other theories, however, account for the effect by increase of the arterial tension, direct action of the drug on the cardiac muscle, stimulation of the vagi—connected by reflex action to the increase of the cardiac pressure,

paralysis of the accelerator nerves of the heart. The last is, however, completely refuted by the fact that the period of slowing is followed by one of acceleration. The period of slowing may, however, be absent when the dose is sufficiently large. With regard to the action on the movements of the heart, there is one point which should be emphasized; it is manifested when the apex of the heart is excised and placed in a solution of digit-alin. This fact tends to show, as the intracardiac ganglia are placed toward the base, that the influence is exerted *directly* on the muscular fibers. The pulse may become dicrotic, or tricentric, with corresponding movements of the heart. With toxic doses the heart stops—tetanically—in systole; the final contraction commencing at the apex. The auricles continue to beat for a time after the ventricles have stopped.

REVIEW OF LITERATURE

Rabies.—Bozzolo¹ differs with Viana, who asserts that those affected with rabies have a tendency to bite themselves. Viana has ground for believing that the virus may be transmitted by an insect. Bozzolo reports a case whose course assumed a chronic appearance, having fever and spinal paralytic symptoms. At autopsy was found a dorsolumbar hemorrhagic state of the cord. Perroncito recalls a similar case which became cured; he believes that rabies may be acquired without paroxysmal symptoms, and proceed along lines of spinal irritation, congestion, and parenchymatous destruction. Perroncito agrees as to the probability of transmission of rabies by insect bite. He mentions a spurious form of rabies, which in dogs is brought about through *Tenia echinococcus*. Pagliani questions the origin of a modified rabies due to Pasteur injections, and asks whether the spinal symptoms noted after the disappearance of paroxysmal attacks could be the result of such treatment? Abba has noted little tendency of patients to bite themselves. [T.H.E.]

Theory of Heart Failure.—G. Hoffmann² gives a mechanical explanation of cardiac compensation. Taking mitral insufficiency as an example, he shows that, before right-sided hypertrophy occurs, the accumulation of regurgitated blood would soon lead to heart failure and death. He explains the nonoccurrence of this by the fact that a diminished amount of blood is sent through the circulation, and on its return to the heart, meets the regurgitated blood, thus making up the normal quantity for the right ventricle to pump through the lungs into the left auricle. There thus occurs merely an oscillation of the regurgitated amount of blood between the right and left sides of the heart, without putting any extra work on the right ventricle. The hypertrophy of the heart muscle is therefore not due to overwork. Hoffmann looks upon such hypertrophy as being a localization of a constitutional disease, just as the valvular lesion itself is such a localization. The process is compared to the trophic disturbances in muscles associated with diseased bones or joints. The author claims that his theory is supported by the fact that the hypertrophied heart finally degenerates; no healthy muscle, according to him, should degenerate. [B.K.]

Subdural Antitetanic Serum Injections in Cases of Tetanus.—J. A. Sicard³ reports 3 cures of grave cases of tetanus by means of lumbar injections of antitetanic serum. He combines large doses of chloral by rectum with the antitoxin. He prescribes the latter in the following manner: From 5 cc. to 10 cc. are injected into varying depths immediately around the seat of injury. From 15 cc. to 20 cc. are injected in such a manner as to come in direct contact with the peripheral nerve trunks, both large and small; especially those nerve trunks are to be taken into consideration which pass through the injured region. From 15 cc. to 20 cc. are to be injected slowly beneath the arachnoid of the lumbar cord at a temperature of from 37° to 38° C. After 48 hours all 3 methods of treatment may be repeated. He has found that relatively high doses of antitetanic serum may be injected into the sub-

arachnoid space (50 cc. and more within 10 minutes to 15 minutes) without any bad symptoms on the part of the patient. In animals he has found this method more active than subcutaneous, but less so than intracerebral, but the latter cannot be used in man on account of its dangers. [E.L.]

Anomalous Cases of Gastric Disease.—I. D. Dunham⁴ gives notes on several cases of gastric disease in which the symptoms were those usually found in connection with some lesion of that viscus other than the one actually present. Case I was in a man of 55, where anemia without emaciation, absence of lactic acid, presence of hydrochloric acid, a total acidity of 98, and dilation of the stomach, led to the diagnosis of stricture from pyloric ulcer. Rapid failure and death before operation occurred, and autopsy revealed a scirrhus carcinoma of the pylorus. Case II was in a woman of 66. Anemia, tumor in the pyloric region, absence of hydrochloric acid, low total acidity, and presence of lactic acid, led to the diagnosis of pyloric carcinoma. Operation revealed a gallstone impinging upon the stomach at the pylorus. In a third case, the subjective symptoms resembled those of hyperchlorhydria. Examination of a test-meal showed the total acidity to be zero. Treatment for achylia gastrica led to complete cure. The fourth case presented a fairly clear picture of carcinoma of the stomach, but examination of a test-meal led to a correct diagnosis of gastric ulcer. These cases are of value in emphasizing the departure from general rules that may be found in the symptom-complex of disorders of the stomach. [A.G.E.]

Epidemic Nephritis.—This occurrence is rare, and when observed is usually laid at the door of scarlatina, perhaps an abortive or atypical manifestation of the same, says Bonanome.⁵ Struempell agrees, but the author suggests a second possible causation, and admitting a paucity of recorded instances from which to generalize, calls attention to circumstances eliminating the fever mentioned as a factor in the epidemic, while the distribution of new cases is often such as to bring out the appearance of contagiousness. He details a number of cases in such a relation noted in 1898. Opinions of Baginski, and others, lead one to suspect some microorganism as an exciting cause. Cases of scarlatinous angina not accompanied by an exanthem are quoted. If these are true reports, it would be possible that the renal epithelium could suffer a limited invasion. [T.H.E.]

Therapeutic Indications in Infective Cholelithiasis.—M. A. Chauffard⁶ maintains that some cases of infective cholelithiasis should be operated on at once, on account of the severity of the symptoms. In other cases operation should be the last resort, on account of age or great obesity. In still others the medical treatment should be tried first, and frequently yields good results. The decision to operate should be the result of a careful consideration of all the symptoms. The most important ones are the type of fever (intermittent, remittent or continuous), the degree and type of leukocytosis, biliary retention, local signs of suppuration, and the general state of the patient. In the medical treatment the first indication is to reduce intestinal fermentation. This may be done by placing the patient on milk diet, or even water diet in severe cases. Locally, hot or cold applications may be employed. An attempt should be made to obtain antiseptics of the biliary passages, the means employed being some form of salicylic medication. [B.K.]

The Behavior of Typhoid Bacilli in Milk and Its Products.—R. Bassenger⁷ reports his experiments from Koch's laboratory concerning the viability of typhoid bacilli in milk and its side-products. He found that heating milk to 60° C. and keeping it there for 5 minutes is sufficient to kill all the typhoid bacilli; that earthen vessels are more suitable for this purpose than iron or agateware dishes; that typhoid bacilli are killed in uncooked milk through its acids (lactic, butyric, and formic acids, etc.) so soon as these acids are present in greater quantities than 0.3% to 0.4% and have acted for 24 hours; that they are killed in butter, buttermilk, and whey under the same conditions; that when milk is centrifugated for its cream for

the purpose of churning butter, the greater number of the typhoid bacilli enter the cream and are worked up with it into butter; there they remain virulent until the above mentioned acids are formed in large enough quantities and have acted sufficiently long. They are virulent during most of the time that the butter is of good taste. [E.L.]

The Hospital Isolation of Scarlet Fever.—A. M. Fraser,¹ in a presidential address to medical officers of health, raises the question as to whether the results of hospital isolation of scarlet fever are such as to justify the large sums annually expended for that purpose. From the comparison of the mortality of scarlet fever and the amount expended annually on hospital isolation, he concludes that the expenditure is out of all proportion to the importance of the disease. Statistics are quoted to show that the advantages from hospital treatment as regards recovery are practically nil. Complications occurring in hospital patients are claimed to be far more numerous than in patients treated at their homes. From these statements the conclusion is reached that the only logical reason for the existence of hospitals must be based on the supposition that they do good by preventing the spread of the disease. Nineteen years' experience in Portsmouth has failed, however, to show that hospital isolation has exercised any restraining influence on the disease. The occurrence of return cases in which the disease is contracted from patients discharged from hospitals is considered to be one of the strongest evidences of the failure of the system in question. Fraser concludes that the hospital isolation of scarlet fever cases in large towns is not to be commended. [A.G.E.]

Impotence and Tobaccoism.—G. Petit² shows from experiments on animals that the effect of overuse of tobacco is seen in a temporary depression of sexual feeling. He believes this action of nicotin is rendered upon the medulla. He notices that in addition to nicotin, tobacco fumes produce many other toxic effects. These have a pronounced influence on the medullary nerve tracts. And local disturbances of the genital system are to be recognized. There is swelling of the epididymis, and a congestion generalized in the testicle, while the seminal vesicles show epithelial proliferation, desquamation, and, in chronic cases, become sclerotic. These channels, with prolongation of the toxic influence, appear devoid of any spermatozoons. It is of value to establish a relation between these experiments on animals and conditions as they may exist in man. [T.H.E.]

Adams-Stokes' Disease.—Percy Kidd³ reports a case occurring in a woman of 58; the symptoms are summarized as follows: Weakness, fainting fits, vomiting, swelling of the feet and legs, headache, sharp pain around the heart, slight hacking cough, occasional night-sweats, swelling of the abdomen at times, and increased stoutness. The fits are described as follows: The patient suddenly cried out, head retracted, pupils widely dilated, face cyanosed, pulse imperceptible for 40 seconds, unconsciousness complete, her body rigid and extended, incontinence of urine, and on recovery, the pulse, which before ranged from 25 to 28, rose to 52; the convulsions lasted 5 minutes. This case is considered typical, and reference is made to others that have been reported, the first being by Robert Adams, of Dublin, in 1827. In this instance the pulse-rate ranged about 30 per minute. Reference is next paid the disease by W. Stokes, and the first case reported by him was described as having repeated pseudoapoplectic attacks, not followed by paralysis, slow pulse with valve murmur. The slow pulse and fainting fits are characteristic of this affection. [A.B.C.]

Albuminuria of Puberty.—A. Pribram⁴ gives a review of this condition. It occurs at the age of puberty in persons who usually show signs of weakness, anemia, inability to perform much work, etc. It occurs just at that period when the greatest growth in stature takes place. It often shows a disposition to run in families. An invariable characteristic of albuminuria of puberty is that it occurs in the erect position, and disappears or is much lessened when the patient lies down for some time.

The specific gravity of the urine is unusually high. Urea, uric acid, and the alkalies, especially potassium, are all increased to a considerable extent. The author believes that this condition is probably dependent on some abnormality in the growth and development of the bone marrow, and sees a possible analogy to the occurrence of Bence-Jones' albumin in multiple myelomas of the bone marrow. The prognosis must be carefully made. Disappearance of the albumin in the recumbent position, with absence of casts, and with a high specific gravity, are favorable signs. The treatment, as outlined by Pribram, consists in prolonged rest in the recumbent position, with very gradual return to the erect position, subject to repeated examinations of the urine. All mental exertion should be avoided, the patients being taken from school. The diet may be a mixed one, including meat. [B.K.]

Syphilitic Anemia and Icterus.—Considerable clinical experience has led F. Samberger¹ to conclude that in the initial stages of syphilis the poison exerts its deleterious influence partly upon the red blood cells, and partly upon the liver cells. Depending upon the intensity of this poison, an alimentary glycosuria, and a urobilinuria, or jaundice, are produced. The longer the disease is without treatment the more powerful the poison becomes. The cause of these disturbances does not lie in the inability of the liver to manufacture the coloring material, but rather in the inability of the liver cells to retain them. As the result of the hemolysis, there is also an increase in the amount of coloring material. The jaundice is therefore hepatogenic. Concerning mercury and its mode of action in syphilis, the author believes it acts in 2 ways. It acts as an antiseptic against the contagium of syphilis and destroys red blood cells, thus inciting the hematopoietic organs to greater activity, and therefore rapidly overcomes the anemic state of the disease. [E.L.]

Angioneurotic Edema.—J. Burnet² defines this peculiar affection as a circumscribed swelling associated with changes of sensation in the part affected, and occasioned by a vasomotor neurosis. The true sites of its origin are no doubt the vasomotor centers of the medulla and cord. The condition is usually, if not always, met with in women, and in those whose nervous stability is readily upset. Burnet makes the following clinical classification of cases: 1. Traumatic. 2. Purely neurotic. 3. Menopausal. Examples of each of these types are cited. In the former the onset of edema may be months or even years after the injury, which is usually brooded over by the patient, though it may have been trivial in character. Treatment should be directed toward lowering the blood-pressure. Bromids accomplish as much as any drug. Local applications are of service in relieving disturbances of sensation. Ichthyol is contraindicated. The principle point in treatment, however, is to gain the patient's confidence, assure her that the condition is not serious, and that she will soon recover. Burnet emphasizes the importance of reporting all cases of this little understood affection. [A.G.E.]

EDITORIAL COMMENT

Movable Kidney and Enteroptosis.—The wide differences of opinion which exist as to the advisability of operative treatment for movable kidney must be confusing to young practitioners. A few years ago, immediately after the introduction of nephropexy, practically everyone considered the existence of movable kidney an indication for operation. At the present time many take the extreme opposite view and advise operation in few, if any cases. Aaron,³ of Detroit, believes that 95% of cases can be relieved by a properly fitting abdominal binder; that enteroptosis almost always coexists with movable kidney, and he calls attention to the

¹ Public Health, January, 1904.² Il Policlinico (Rome), No. 8, 1904.³ The Lancet, February 13, 1904.⁴ Prager med. Woch., 1904, Nos. 1 and 3.¹ Archiv für Dermatologie u. Syphilis, 1903, lxvii, 87.² International Clinics, Vol. iv, Thirteenth Series, 1904.³ American Medicine, 1903, Vol. vi, page 898.

importance of mapping out the position of the stomach, liver, and all other abdominal organs, as well as the kidney, and adapting the support accordingly. Larabee¹ reports a study of 112 cases of movable kidney in the Out-Patient Department of the Boston City Hospital and of this number he did not find a single one in which he considered operation advisable. Two of his patients had been operated upon previously, without relief. He believes that enteroptosis generally coexists, and the use of a bandage will often tide a patient over a period of poor health or debility and when she has recovered to normal health and flesh the symptoms usually cease. In most of his cases no treatment was considered necessary. In a paper on "Nervous Phenomena Associated with Movable Kidney," by Dr. Wharton Sinkler,² and the discussion following it before the section on Nervous and Mental Diseases of the American Medical Association, the general trend of opinion seemed to favor operation in cases of much displacement of the kidney in which other treatment had been faithfully tried without benefit. Considerable difference of opinion was expressed as to the influence of operation on neurasthenic symptoms, some of the neurologists stating that they never hesitated to send neurasthenics to the surgeon, while others believed that the treatment should be mainly along neurologic lines. It was quite generally believed that operation is of some value in certain cases. As might be expected, many surgeons take almost opposite ground from that of the internists and believe that practically all cases of movable kidney should be operated upon. Goelet³ is one of these, and he points out many reasons why that operation has proved a failure in the hands of some surgeons. Among the causes of failure which he mentioned were: Incomplete detachment of the fatty capsule, leaving the kidney adherent to the colon, which drags upon it; improper insertion of sutures or their too early removal or absorption, or attachment too low down. Among postoperative influences he mentions the loosening of the attachment by a violent vomiting, coughing, or early exertion, or by turning on the opposite side, or assuming the erect position too soon. He advises operation in a large proportion of cases of movability. On the other hand, many prominent surgeons agree with the internists that operation is not advisable in the majority of cases. Morris⁴ says that when movable kidney is associated with enteroptosis operation is usually contraindicated, and Keen has shown that in a large percentage of cases operative results are unsatisfactory. Careful observers have estimated that from 60% to 80% of all women over 45 years of age have movable kidney, and we feel that it would be too extreme to say that operation is indicated in all or even a small proportion of these cases. Some of the most able of both internists and surgeons, including such men as Osler and Morris, believe that operation is advisable in certain cases of extreme movability, though not indicated in the majority of cases. Whenever the movability gives rise to crises of pain, symptoms from pressures on the intestines, the pyloric end of the stomach, or the common bile duct, when hydronephrosis is caused by kinking of the ureter, or twisting of the pedicle occurs, there seems to be little doubt as to the advisability of operation; and when the dragging of the kidney gives rise to symptoms which cannot be relieved by other means, operation should be seriously considered. No doubt in a great proportion of the cases in which no relief has been experienced following nephropexy, the failure has been due to injudicious selection of cases, and operation in cases in which the symptoms were dependent fully as much upon general enteroptosis as to the movability of the kidney alone.

REVIEW OF LITERATURE

Hepatic Drainage.—E. Berger¹ concludes as follows: 1. Drainage is preferred to choledochotomy closed with sutures because it hastens cure of the existing cholangitis, and the operation is done more rapidly. 2. Drainage is indicated in cholangitis when it is not possible to remove all the stones from the common and hepatic ducts at the time of the operation. 3. It is the safest and best method even in cases in which the histologic and operative findings show no stones in the deep gall passage. 4. It is contraindicated in acute choledochus obstruction (where one should really not operate at all), and in acute suppurative cholangitis, because there is danger of infection spreading downward. 5. The incision is best made at the supraduodenal portion of the choledochus duct, encysted concretions necessitate special incision for their removal. 6. Since in hepatic drainage stones escape in about 17% of all cases after operation, it prevents subsequent operations. Recurrence of gall-stones is the exception when drainage has been carried out. 7. With drainage diffuse cholangitis subsides even when stones still exist high up in the liver. 8. With hepatic drainage the mortality does not exceed 2% or 3%. 9. Cholangitis in the larger branches of the hepatic duct, long-continued icterus, and cholemia, liver cirrhosis, pancreas affections, enterobiliary fistulas, and extensive adhesions increase the dangers. 10. In diffuse cholangitis, carcinoma of the pancreas or gall passages, and liver abscess, the mortality is nearly 100%. This is not due to operation, but to prolonged internal cure. If in choledochus duct obstruction, 3 months at Carlsbad fails to give relief, he says an operation is necessary. [A.B.C.]

Operation in Cancer of the Stomach.—B. G. A. Moynihan² says that admitting the difficulties in the way of earlier recognition of cancer of the stomach, the present results of surgical treatment of that condition are not so satisfactory as they ought to be. The questions in urgent need of settlement are those of the relative values of palliative operations and gastrectomy. The larger part of Moynihan's paper is devoted to a consideration of the statistics furnished by Crönlein and von Mikulicz, the former reporting 264 cases in 21 years, the latter 458 cases in 10 years. The results of different methods of treatment by these 2 observers differ but slightly, the average length of life after the beginning of the disease being, in nonoperated cases, 12 months; after exploratory laparotomy, 13½ months; after gastroenterostomy, 15 months; after gastrectomy, 25½ months. Moynihan is very outspoken in his advocacy of gastrectomy. The advantages of gastrectomy as compared with gastroenterostomy are: (1) In the most competent hands its mortality is not more, but is even less; (2) the prolongation of life is 10 months greater; (3) the comfort, general health, appetite, and well-being of the patient are all emphatically better; (4) the patient has always a chance, even though it is of the slenderest, of a complete recovery from his disease. [A.G.E.]

Abdominal Aponeurosis and the Best Method of Approximation.—Kennelm Winslow³ reviews the various methods that have been employed to effect union of the abdominal parietes, especially in the radical cure of umbilical and other hernias, and advocates an overlapping of the abdominal aponeuroses in the closing of abdominal wounds, as in appendicitis, hernia, etc., thus giving a stronger parietal wall for the prevention of hernia. He says: When we see how successful have been the special operations of Halsted and Mayo by the method of overlapping the aponeuroses for the cure of hernia, why not apply the same operations to the closure of all abdominal incisions for the prevention of hernia? Incisions for attacking the gallbladder, the middle line incisions, and incisions in any part of the belly wall, can be closed to best advantage in consonance with anatomic reasoning and clinical results by this method. This effects a closure by overlapping and therein strengthening the abdominal wall by its chief covering, and thus insures the prevention of hernia. [A.B.C.]

Acute Mediastinitis, Due to Ingested Fishbone: Necropsy.—Armando de Córdoba⁴ relates the case. A laborer of 20 swallowed a fishbone of small size, immediately after

which he suffered pain in the epigastrium. In a few days his temperature rose to 40.2° C. The latter symptom persisting, and the patient having been in a malarial district, quinin was given, but the temperature curve remained erratic, and chills appeared, alternating with sweats. Blood-examinations repeatedly revealed no parasites. Symptoms of precordial tension developed and slight dyspnea; the sputum contained no pneumococcus, nor bacillus of Koch nor of Pfeiffer. Amid the chances of (1) phlebitis of the portal vein, (2) gastric torsion or trauma, (3) acute mediastinitis, the last seemed probable. Death occurred and necropsy confirmed the diagnosis of mediastinitis. The postmortem conditions revealed the formation of a mediastinal abscess and an inflammatory exudate in the pleural and pericardial cavities. The esophagus presented an area of necrosis, due to the ingested fishbone. The esophagus was quite adherent to the root of the right lung, where the injury and necrotic area involved bronchus and vein, and where an unorganized clot, evidently hemorrhagic, was found. [T.H.E.]

Operative Removal of Tumors of the Liver.—H. A. Haubold¹ reports a case. The patient was a woman of 26, who had had 2 miscarriages, but absolutely denied specific infection. A tumor the size of an orange could be palpated in the region of the gallbladder; the diagnosis rested between cholelithiasis, duodenal ulcer, and neoplasm of the gallbladder, liver or pylorus, a gumma not being suspected. At operation the tumor was enucleated without serious hemorrhage, the latter being controlled readily by tamponade of gauze and hot salt solution. Cholecystectomy was at the same time performed, the cyst wound in the liver was approximated with deep sutures and drainage established. The recovery of the patient was uneventful, the interesting feature being that a microscopic examination of the removed tumor showed, instead of malignant disease, a simple gumma. He gives a summary of 96 cases of resection of the liver reported by Anschuetz; of this number 75 recovered and 17 died from the operation. The various methods of procedure are enumerated. [A.B.C.]

Nongonorrheal Metastatic Urethritis.—According to F. Porges,² this may arise from: (1) Trauma, such as those caused by continued catheterism; (2) chemic irritation from urethral injections; and (3) communication of an infectious agent (excluding the gonococcus) through coitus or dirty instruments. The author reports a case in which an operation was performed on the anterior urethra, followed by habitual catheterism for a time. A mild catarrhal urethritis occurred, which persisted for 2 or 3 months. At the end of that time, local injections were instituted, which resulted in setting up an acute posterior inflammation. No gonococci could be found in the discharge. Three days later an epididymitis and orchitis developed, and still later an abscess of the prostate gland. Complete recovery occurred in 14 weeks. [B.K.]

Deceptive Abdominal Conditions and the Question of Operation.—A. H. Tubby³ reports a series of cases representing various suppurative abdominal conditions and states (1) that many abdominal lesions are latent in their symptoms for a time and then suddenly become active; (2) that cases commencing actively subside and are apparently getting well and then break out with increased virulence and end fatally, the favorable opportunity of the latent period not having been grasped; (3) that when the general symptoms of suppuration are present, it is sometimes impossible to say with what organ it is connected, and we have no data on which to commence our exploration, which may be of a severe character; and (4) the fear that if we do not find the focus of suppuration we may not, in evacuating it, be able to limit and prevent its spread to the general peritoneal cavity. He then discusses the relation of pulse to temperature, leukocytosis, rigidity, vomiting, adventitious diarrhea and constipation, local tenderness, hematemesis, increased abdominal dullness, effusion of blood beneath the abdominal wall, etc. With reference to rigidity, he states that it is almost always associated with some tenderness, and is a symptom to be carefully watched, particularly if it persists, even in the absence of other abdominal signs, such

as vomiting and severe pain. Rigidity with some tenderness is sufficient ground for operation. [A.B.C.]

Relation of Surgical Pathology to Surgical Diagnosis.—J. C. Bloodgood¹ says that surgical technic is far in advance of surgical diagnosis. In the great majority of instances failure to cure is not the fault of the operative procedure, but is due to the fact that operation has been done at too late a period in the course of the disease. The latter is due to 3 factors: (1) The time during which the lesion has not attracted the attention of the host; (2) the time that the patient delays before seeking advice of the physician; (3) the time spent by the physician in deciding on the treatment to be instituted. In the majority of instances a careful examination of the patient at the time of his first visit will allow one to decide whether delay is justifiable. It is unnecessary and dangerous to delay treatment for exact diagnosis; the question is, not what is the exact nature of the surgical disease, but rather is it, or is it not, a lesion which will allow of delay. The question of tumors is then discussed, as they illustrate very well the need of surgical pathology in order to make a diagnosis, particularly an early diagnosis. The object of surgical pathology, therefore, is to instruct in the positive recognition of surgical lesions by their naked-eye appearances. [A.G.E.]

Perforation of the Urinary Bladder by Appendicial Abscess.—I. S. Stone² reports that a woman of 50 suffered from mild symptoms of appendicitis which were not deemed sufficient to justify operation. Three weeks after the beginning of her illness there was dysuria and cystitis which culminated in the discharge of nearly a pint of pus during 2 days, from the bladder. Following this the symptoms subsided, and 3 months later an examination showed a mass in the site of a former appendicial abscess. The abdomen was opened and it was found that the appendicial abscess had ruptured into the bladder; the omentum had been of great service in securing the attachment of the appendix. When the latter was liberated its distal extremity was found opened and in direct contact with the perivesical tissue; spontaneous closure of the bladder had been effected before operation. The author has collected a report of 30 other cases from as many different surgeons. [A.B.C.]

Acute Inflammation of the Cecum.—Reisinger³ found acute cecitis twice in 350 operations for appendicitis. Its symptom-complex is identical with that of appendicitis, and it is impossible to make a diagnosis before operation. In both cases the appendix was perfectly normal, and the cecum the seat of a gangrenous abscess. In the second case chronic constipation was evidently the cause, but this was no factor in the first case. He discusses the question, Why is the cecum the part of the large intestine constantly affected whenever ulceration and gangrene follow fecal impaction? He explains it by the greater impaction at this point on account of the ileocecal valve, by its lack of mobility as compared with other parts of the large intestine, and by the fact that the posterior wall of the cecum is free of peritoneum, and, therefore, less resistant than other portions. [E.L.]

Bilateral Temporosphenoïdal Abscess.—A. L. Whitehead⁴ reports the case. A woman of 20 was brought under observation in a comatose condition with a purulent discharge from both ears; she had suffered from an intermittent aural discharge for 6 years. For some 3 weeks there had been urgent symptoms, constant headache, dizziness, constipation, mental dulness, vomiting, and finally complete unconsciousness; the temperature had been normal or slightly subnormal. A mastoid operation was done upon the left side, a part of the squamous part of the temporal bone removed and the brain exposed. It did not pulsate. A glass tube was passed in to a depth of three-eighths of an inch, abscess found, and 3½ ounces of pus evacuated. The patient slowly and completely recovered. Two and a half years later there was recurrence of these symptoms, but indicating trouble on the right side. A mastoid operation was now done upon the right side, and a large abscess found in the right temporosphenoïdal lobe, and 3 ounces of pus

⁴ The Lancet, February 13, 1904.

evacuated. The patient again made a slow but complete recovery. In the contained pus of the last abscess the colon bacillus was found. On both occasions the points by which the diagnosis was established were the presence of chronic otorrhea, severe unilateral headache, subnormal temperature, slow pulse, drowsiness progressing to coma, and occasionally vomiting. [A.B.C.]

The Healing of Laparotomy Wounds.—F. W. Bukoemsky¹ has made a series of experiments on animals in order to study the mode of wound-healing after laparotomy. He finds that union of the wound-edges may be perfect, even histologically, provided the edges do not curl inward. It is advisable to employ the finest suturing material, which better enables us to approximate the edges of the wound. The incision should be made laterally from the linea alba, or still better, the linea alba may be completely removed and the broad muscular surfaces united. Since muscle-tissue is well-nourished, such wounds heal promptly. The simpler the suture of an abdominal wound the better, as a rule. The author has often noted that deep sutures are injurious to the tissues, irritating them and producing edema, which may suppurate. The idea of absolute asepsis must be abandoned. Microbes have been found in 90% of wounds healed by first intention. Edema supplies a favorable nutrient medium for bacteria, and therefore deep sutures are best avoided. In placing the sutures, we must guard against tightness, which often results in compression and death of muscular tissues. The lost muscle is then replaced by connective tissue. The best method of sterilizing catgut is by means of dry heat, at 150° C. This kills even spores of anthrax. In general, laparotomy in animals takes a more favorable course if the incision has been short. [L.J.]

Removal of the Prostate by the Suprapubic Route.—B. G. A. Moynihan² reports a series of 12 cases, the ages ranging from 56 to 73; in 4 instances a stone was found in the bladder. A detailed description of the suprapubic operation as revived by Frayer is given. Attention is called to the fact that often after operation there is extreme paroxysmal pain for a few hours, which is usually relieved by a morphin suppository or that drug given hypodermically. At the end of 48 hours the suprapubic tube is removed and the patient allowed to sit up; on the fourth day and each succeeding day a catheter is passed and the bladder freely washed with a dilute carbolic lotion. It is important to get old and feeble men up out of bed as quickly as possible, allowing them to sit in the chair by the end of the first week. Cystitis is combated with urotropin or helmitol. The after-treatment of these cases requires close attention and considerable time. The bladder is washed out daily. In some instances, where the urine is especially foul, a stream of oxygen is passed through the bladder daily. Over the suprapubic wound a tight-fitting impervious cap is placed, having a small leak to permit the escape of gas; this facilitates feeding. The removal of the prostatic portion of the urethra with the tumor produces no untoward complications. [A.B.C.]

The Surgical Treatment of Pulmonary Abscesses.—Karewski³ says the most important causes of long abscesses are croupous and influenzal pneumonia, foreign bodies, septic emboli, invasion from neighboring or distant abscesses, as from liver, kidney, pleural or subphrenic abscesses. The abscesses of influenza are usually multiple and the suppuration chronic. The abscesses produced by foreign bodies should not be operated upon until the causal agent has been removed by bronchoscopy. Empyema is oftener secondary to lung abscess than lung abscess to it. Many abscesses heal spontaneously through perforation into a bronchus, but even after perforation it does not necessarily mean that the patient's condition will be cured. It may continue to suppurate and break out later, and sometimes chronic sepsis will be the result. The indications for an operation exist, therefore, so soon as a diagnosis is made with certainty, and grave general symptoms do not disappear quickly, or if they should, reappear after a spontaneous rupture into a bronchus. Expectant treatment is permissible in young individuals, in small abscesses in the pulmonary apices or in

large abscesses in the base, if they belong to the acute variety, and are not associated with too serious a symptom-complex. [E.L.]

An Experimental Method of Aseptic Gastroenterostomy.—Padula⁴ reports favorable results upon dogs from the following: Laparotomy, suture of the serous and muscular walls of the organs involved, done lengthwise; attachment of a special clamp to the parts sutured, and a second set of similar stitches joining the walls over the clamp. The mucous coats are not included and no connection is established between the first ways and the peritoneal cavity. After a time the clamp cuts through the inner parenchyma and is passed in stool, leaving a satisfactory passage from stomach to intestine. The clamp is flat and square, having 2 opposing edges rolled slightly upward and inward; it is applied by folding tightly shut to catch the tissue and cut into it. [T.H.E.]

The Genesis of Hygroma.—Langemak⁵ says they develop from bursas, although they have begun in regions in which there is no bursa, *e. g.*, over the spinous processes, amputation stumps, etc. The connective tissue from which the bursas develop, especially those that give rise to hygromas, contains also collagen and elastic fibers. He believes hygromas are formed by atrophy of the adiposa, and hypertrophy of the fibrous tissue framework which becomes vascular; this is followed by a deposit of collagen, the accumulated collagen soon liquefies, when it simulated fibrin; this Langemak calls fibrinoid. Radical extirpation of the hygromas only prevents return, he does not favor aspiration and compression. [A.B.C.]

Home Treatment of Suppurative Ear Diseases.—J. C. Beck⁶ says that most individuals suffering from suppurative ear diseases belong to the poorer classes and cannot afford to go daily for treatment. When treated 2 or 3 times a week the accumulated moisture leads to granulation formation and necrosis. To avoid this, Beck has devised a glass tube with a little beak at the end to retract the tragus and enable a whalebone probe to grasp the sterile gauze which is contained in the tube. This is furnished the patient with instructions how to pack the ear with gauze if the dressings become saturated. With this device to be used by the patient or his friends between visits to the physician, much more satisfactory results can be secured than from the occasional dressings by the physician, especially in acute cases. The simple appliance is also very useful in the office practice of the physician. [A.G.E.]

Oxygen-Chloroform Narcosis with the Roth-Draeger Apparatus.—D. Hahn⁷ describes the Roth-Draeger apparatus and the manner of using it, minutely. He himself has employed it for purposes of narcosis in 77 cases, and praises it. He considers it superior to the drop method employed so generally; as a special point of preference over all others he mentions its easy applicability, the quiet which exists all through the narcosis and the absence of all excitement even in cases where this is to be expected (alcoholism).

GYNECOLOGY AND OBSTETRICS

WILMER KRUSEN

FRANK C. HAMMOND

REVIEW OF LITERATURE

Vaginal Tampons of Value in Vomiting of Pregnancy.

—A Pettazi⁸ believes such vomiting due to uterine lesion, and has found it possible to arrest the disturbing symptoms by using a vaginal tampon of ichthyol and glycerin. Granting the cause of vomiting to be seated in the uterine wall, gestation brings about an unusual and excessive pressure on the vessels of the blood-vascular system therein, in consequence of which the reflex becomes established through the sympathetic nerve supply. A cure is possible if the original lesion be metritis; if it be a false position of the uterus which causes the increased pressure on the vessels, a cure is not so readily to be obtained. [T.H.E.]

Tuberculous Disease of the Fallopian Tubes.—A. W. W. Lea⁹ reports 4 cases of this kind treated by operation. In

⁹ British Med. Jour., October 17, 1903.

cases 1 and 2 there were present many miliary tubercles and adhesions. Both tubes and ovaries were removed, and both patients made a good recovery, and are still in excellent health. In case 3 both tubes were distended with pus and with the ovaries were removed, and the patient rapidly regained perfect health. In the fourth case the tubal affection was accompanied by tuberculous peritonitis, and the removal of the tubes did not seem to have any effect upon the course of the peritoneal disease. The patient died 3 weeks later. The operative treatment which consists essentially of the removal of both tubes, holds out a prospect of cure if the tubes are the primary seat of the disease, and are removed early; but in acute abdominal tuberculosis and the secondary invasion of the tubes as in case 4, the value of operative interference is very doubtful. [W.K.]

Paget's Disease.—M. A. Tehlenow,¹ after an exhaustive study of the various aspects of Paget's disease of the nipple, arrives at the following convictions: 1. Paget's disease belongs to the group of cancerous skin affections. 2. Clinically the disease presents features peculiar to itself and allowing it to be differentiated from eczema and other similar conditions. 3. Paget's disease is not confined to the female sex; neither is it invariably located on the nipple, other parts being occasionally attacked. 4. Diagnosis in the later stages offers few stumbling-stones. Incipient Paget's disease may, however, be mistaken for eczema, etc. Histologic examination will in such cases give the decision. 5. The origin of the affection is still a matter of conjecture, although a parasitic etiology is probable, as in other forms of cancer. 6. The course is usually chronic, the prognosis in general favorable, especially under proper treatment, which is chiefly surgical. [L.J.]

Fibromyoma of the Uterus with Visceral Metastases.—E. Devic and L. Gallavardin² give extended clinical, autopsy, and histologic notes of a case which is a new contribution to the study of malignant leiomyoma. The patient was a woman of 55, who, for 7 months had suffered from lumbar and abdominal pain. Ascites was present, also a pleural effusion, and the uterus was enlarged and immobile. At autopsy the uterus was found to be quadrupled in size and contained submucous and interstitial fibroids with extension to the surrounding structures, especially the rectum. The omentum, peritoneum, liver, diaphragm, and lungs contained secondary growths. Microscopic examination showed the uterine tumor to have the structure of a malignant leiomyoma, this also being true of the metastases. Analogous cases are very rare, only 2 others being mentioned. The histology of this tumor differed somewhat from that of a cutaneous leiomyoma previously reported, this leading the authors to state that there may be many histologic varieties of malignant leiomyomas depending on the age, the degree of malignancy, and the site of origin. [A.G.E.]

Acute Yellow Atrophy of the Liver and Pregnancy.—I. J. Lisiansky³ reports a case and reviews the literature. He concludes: 1. Frequently icterus gravis has been confounded with acute yellow atrophy of the liver, although the two are distinct. 2. The most deserving theory of pathogenesis of yellow atrophy is that of intoxication from the intestinal contents. 3. Yellow atrophy is not invariably fatal, even in its severer grades. 4. Every pregnant woman with icterus should be under the strictest medical control, especial attention being given to the quantity and quality of the urine. 5. As to management, it seems that in the early stages of the disease, interruption of pregnancy may be beneficial. Such a course is contraindicated in the advanced phases of yellow hepatic atrophy. [L.J.]

Hematology of Gestation, Etc.—E. Alfieri⁴ publishes tests of 211 cases. During the later months of pregnancy there is a diminution of iron in direct relation to that of the hemoglobin and the erythrocytes, varying from $\frac{1}{10}$ to $\frac{1}{2}$. In the first week of the puerperium there occurs a greater drop in the ferric constituents, followed by a slow, perhaps unequal, rise to the normal relations after several months. Yet pregnancy may offer other types than the foregoing, which, if not really path-

ologic at times, approach it and may be described as the "chlorotic" and the "pernicious." The newborn reflects maternal variations so far as to follow ferric reductions in percentage within certain limits, and at the same time resists as great a reduction in hemoglobin as in the number of red blood cells and the actual ferric value. In the mother there is a more pronounced resiliency shown during the puerperium if the anemia has been of the pernicious type than of the chlorotic, in a measure explainable by etiologic factors as now known. The writer points out a disproportion in the hematic and the hemometric results, as seen above. [T.H.E.]

The Toxemia of Pregnancy.—W. S. Stone¹ discusses at length the toxemia of pregnancy with 3 illustrative cases, and analyzes especially the symptoms of the group of cases described as pernicious vomiting of pregnancy. The temperature may be subnormal, normal, slightly raised, or high in the last stages of the disease. The pulse also may remain nearly normal until an advanced stage. The character of the vomitus is a better index of the progress of the disease, changing from an almost colorless mucus to a thin blackish fluid, due to disintegrated blood and bile. In the toxemia of pregnancy there will be found in the urine an excess of ammonia, or amidoacid nitrogen, together with a loss of urea nitrogen. The recognition of the toxemic origin of hyperemesis gravidarum should prevent our trying any of a long list of drugs often recommended and limit the treatment to a few, such as calomel and salines, that we know to be useful. There should be absolute abstinence from either food or drink by stomach until improvement has begun. Nutritive enemata may be used; in some cases it may be best to wash out the stomach one or more times. Our chief reliance, however, should be placed in the injection of hot normal saline solution into the rectum at frequent intervals. It may be advisable to add a half ounce or an ounce of whisky to some of the injections; or, in some cases, it may be advisable to employ continuous irrigation of the rectum with hot saline solution for half an hour every 2 or 3 hours. Occasionally the injection of saline solution, either subcutaneously or directly into the veins, may be used with good effect. [W.K.]

Treatment of the Umbilical Stump in the Newborn.—After the child receives its first bath, P. Ahlfeld² relegates the stump as close to the root as possible, and then cuts off the surplus cord. Then the stump and surrounding abdomen is washed with 90% alcohol. The stump is then covered with sterile absorbent cotton, and an abdominal binder applied. The daily bath is omitted, the child being washed instead, until the stump separates. The primary dressing is not changed, unless it becomes soiled from urine, when a fresh binder is applied, and the wet cotton replaced by dry. The author has never had an infected umbilical stump since employing this method. [B.K.]

Cancerous Metamorphosis of Dermoid Cysts.—T. W. Zeleuski³ reviews the present state of the question regarding cancer originating in ovarian dermoid cysts. He sums up thus: 1. Ovarian dermoids, if they become cancerous, invariably produce the flat epithelial type, which arises from the dermal covering of the cyst. 2. Cancer attacks most frequently multilocular dermoids of the ovary and is usually unilateral. So far, no bilateral cancerous degeneration of ovarian dermoids has been recorded. 3. The victims are generally advanced in years, and the cancer takes a very malignant course, ending fatally either from perforations of adjacent organs or from cachexia. 4. Ascites seems to be invariably absent in this variety of cancer. 5. The diagnosis is difficult, and the only rational treatment is preventive, aiming at removal of dermoid cysts, whenever such are recognized, before malignant changes have supervened. [L.J.]

Tuberculosis of the Uterus and Appendages.—J. H. Targett⁴ states that in 500 necropsies of females who died of tuberculosis in Brompton Hospital for Consumptives, the genital organs of 7.7% were found affected. Of the organs affected in genital tuberculosis the fallopian tubes are to be found the most frequently and are involved in about 90% of the cases;

the forms may be diffuse military tuberculous salpingitis, caseous tuberculous salpingitis, and tuberculous pyosalpinx. Tuberculosis of the uterus is usually the result of infection from the tubes. There is great difficulty in accurate diagnosis of acute tuberculosis of the tubes, but in chronic lesions there is much better chance of a correct diagnosis. The previous history is of importance, and the absence of other adequate causes of the disease is a valuable guide. Sterility is usually present in the chronic forms of tuberculous salpingitis, especially pyosalpinx. On the other hand pregnancy seems to hasten the development of tuberculous peritonitis, not a few cases of which follow rapidly upon a confinement, and they often do badly. Dysmenorrhea is a common symptom and the absence of pelvic pain is worthy of note. It may be stated generally that the tuberculous process is unaccompanied by pain so long as it remains free of secondary infections by pyogenic organisms. [W.K.]

TREATMENT

SOLOMON SOLIS COHEN

L. F. APPLEMAN

E. LINDAUER

EDITORIAL COMMENT

Treatment of "Cold in the Head."—A Toronto subscriber asks "what remedies are best to use, when from ordinary 'cold in the head' the patient is quite unable to breathe through the nose, and suffers in consequence." He had "thought of using adrenalin as a spray, or possibly a snuff containing cocain, but would like very much to have (our) opinion as to the advisability of using either of these remedies." Adrenalin, or suprarenalin, whichever is easier to obtain—or in case of inability to get either of these, a filtered, saturated aqueous solution, made extemporaneously from the suprarenal substance prepared by any reputable manufacturer—is the best of all palliatives for the acute obstruction of the nasal passages described by our correspondent. In order not to waste the expensive drug, the parts should first be cleansed thoroughly from accumulated mucus or mucopus, either by a douche of hot saline solution (sodium chlorid, 0.77% in distilled water), or of hot milk to which sodium chlorid in the proportion of 3 grains to the ounce has been added, or by an alkaline detergent spray. The spray solution should be warmed, though it need not be hot. By "warm" is to be understood a temperature of about 90° F., and by "hot" a temperature of more than 100° F. In douching, the patient's head should be bent well forward over a basin to avoid entrance of the solution or of the secretions that it washes away, into the eustachian tube. Of alkaline detergent solutions, the following formula may stand as a type:

Sodium borate 5 grains
Sodium bicarbonate 5 grains
Pure carbolic acid 1 grain
Glycerin 4 fluidrams
Infusion of tar sufficient to make . . . 4 fluidounces
Mix.

In place of the infusion of tar the preparation known as "liquor carbonis detergens," which is an emulsion of purified coaltar and tincture of soapbark (guillala), may be used in the proportion of from 2 drops to 4 drops to the ounce of water, depending somewhat upon the strength of the preparation—for which there is no pharmacopeial standard. The French preparation, known as "coaltar saponin," is a diluted emulsion of this kind, and of this from 10 drops to 15 drops to the ounce may be used. The wellknown "Dobell's solution" is also available, and there are a number of eligible proprietary solutions on the market to which a sufficient dose of the sodium salts may be added, if tar preparations are not available. The suprarenalin solution may be applied topically, in the strength of one part of suprarenalin to one thousand parts of water, by means of a cot-

ton wad firmly twisted on a delicate carrier of wire, and the relief thus given frequently lasts from 12 to 24 hours. Or the patient may be allowed to spray the nasal passages very lightly, using a solution of from one part in four thousand to one part in eight thousand. After the suprarenalin has been applied, a warm oil-spray should be used as a protective to the parts. An eligible formula is the following:

Menthol 5 grains
Benzoinated liquid petrolatum 1 ounce

In certain cases, from one drop to twenty drops of eucalyptol or a few drops of oil of gaultheria or of oil of birch may be added with benefit and may contribute likewise to the patient's sense of comfort. Other fragrant or aromatic oils, as cloves, sassafras, and the like, may be used in addition if desired. Internally, the use of minute doses of atropin has for 20 years been advocated by the writer of this paragraph, and the practice is now almost universally followed by the laity, through the medium of what they call "rhinitis," believing that term to be the name of a drug. Many physicians who have prescribed the so-called "rhinitis tablets" marketed by various manufacturers, have themselves to blame for the fact that their patients resort to these tablets on self-prescription or the advice of friends; in very many cases when such drugging is not only useless but positively counterindicated. We have personal knowledge of more than one case of pneumonia or other form of influenza in which valuable time in sending for the physician has been lost through such self-medication. Physicians ought never to prescribe these ready-made preparations, but should write their own prescriptions, and in such doses as best suit the individual case. A useful combination is represented by the formula following, which should, however, be varied to meet the necessities of individual cases. Age, the condition of the eyes, drug susceptibilities, cardiac, pulmonary, and renal conditions must all be taken into consideration. The prescription here given, containing $\frac{1}{2000}$ grain of atropin in each dose, is for an adult.

Atropin sulfate $\frac{1}{2000}$ grain
Camphor 2 grains
Quinin 5 grains
[Balsam of Peru or other suitable excipient, a sufficient quantity]

Mix. Make into 20 doses in pills, tablets, capsules, cachets, or powders, diluted with sufficient milk-sugar.

The dose is one (capsule) given usually from about every half-hour to every four hours, according to the effect. At first the intervals between doses may be even shorter than 30 minutes, and when relief is obtained they may be lengthened—to even more than four hours. Sometimes it is advisable to use tincture of belladonna instead of atropin. As a rule the belladonna is preferable for children, and so little as one-tenth drop every ten minutes for a certain number of minutes until effective, may be given. Sometimes it is advisable to use the camphor and sometimes the latter should be left out. The same may be said as to quinin, salol, and other drugs. Ammonium salicylate is often the best drug for internal use. It should be given in a pepsinated vehicle. A good purge at the beginning of an attack is often highly useful. A good sweat often cuts the attack short, and when there is no counterindication, pilocarpin in appropriate doses may be used in conjunction with external heat to produce the free perspiration desired. Sometimes strychnin is necessary. Cocain should never be employed in any case or under any circumstances, except it be the only cardiac stimulant available in an emergency that calls for such line of treatment. Camphor, however, is infinitely superior for this purpose. A cocain habit has often been induced by the use of cocain snuffs and solutions prescribed by physicians or sold over the drug counter for the relief of "colds."

REVIEW OF LITERATURE

Pure Carbolic Acid in the Treatment of Smallpox.—

J. T. Neech and J. F. Hodgson¹ state that they have employed this drug in the treatment of 136 cases of smallpox with a mortality of 3.6%; 22 of these cases were of the confluent type, 12 semiconfluent, and 103 were discrete. The method employed was as follows: The pure carbolic acid was applied with a small camel's hair brush to the vesicles over a certain area of the body, which had commenced with the face and head until the whole of the vesicles had been touched. These applications were continued until the vesicles showed signs of drying up or aborting. Considerable time is required to do this carefully and thoroughly. Care must be taken to avoid touching the healthy skin with the acid. Though a careful watch was kept for the appearance of toxic symptoms, only 2 patients showed carboloria. In some cases only one side of the patient was treated with the carbolic acid, and in all such instances it was plainly seen that carbolic acid gave the best results. The application of the acid caused very slight transitory pain and relieved the intense irritation. The effect appeared to be local, the pustules rapidly shriveled and scabbed, and the further development of the papules and vesicles was aborted. All the vesicles had formed into scabs at from 5 to 10 days, and in from 10 to 18 days the scabs had fallen off, except on the palms of the hands and soles of the feet. The tendency to the formation of scars was not nearly so great as in other forms of treatment, the offensive odor was prevented, and the secondary rise of temperature was prevented owing to there being little or no toxic material absorbed into the vesicles. On the whole, the authors are pleased with this method of treatment. [A.B.C.]

Necessity for Muscular Exercise.—Luther Halsey Gulick² points out that those conditions under which the body was given its present size, shape, and structure are in general the conditions adapted to maintaining the fullest functional activity. During the unnumbered years of evolutionary time, muscular exercise in labor, war, or the chase, has been one of the major elements of human experience. Upon neuromuscular ability the race has depended for survival, even when its ancestors were in a condition of development yet more elementary than that of savage life. A biologist, having brought to him a human body, and being asked for a statement of its functions from an examination of the structure would say that both in form and function the organism must have been adapted to a life of considerable muscular exertion; that this appeared, first, from the proportions of the muscular system; that the lungs as well as the heart indicated far more capacity than would be needed for a life exclusively or even largely sedentary; and, finally, that the nervous system was designed predominantly for the initiation or control of muscular movements. The health of such an organism depends upon the balanced cooperation of all its parts. These parts have become adjusted to a certain general balance in the activities of the nutritive, neural, and muscular tissues. No argument is necessary to the evolutionist to show that the necessity for muscular exercise has been constant and predominant throughout the whole history of the life of the species; that it has been so constant and so large a factor in adjustment to the total environment as to have had a chief share in determining the character of the organism itself; and that those conditions which have been decisive in determining the form and functions of the organism are the conditions in which it functionates the best. The argument for muscular exercise from the standpoint of evolution is thus the strongest that can be presented. The environment of the organism cannot be changed in other respects with impunity. The conditions of human life in civilized countries have changed more since the development of the steam-engine than they had for thousands of years previously. In the United States the proportion of steam-power to manual labor is represented by a steam-engine of 11½ horse-power to every male adult inhabitant. The bulk of the heavy work in the civilized world is done by machinery and not by human muscles. There is still a good deal of muscular work per-

formed, but it is decreasing rapidly. It is least among the most civilized peoples, and among these peoples is least among the most civilized classes. The management of machinery demands not muscular force, but muscular skill and intelligence. In the handling of machinery the tendency is to have individuals make comparatively few movements many times. The more general activities of early farm life called for a far more varied set of muscular movements. These, and other factors, according to Gulick, make conscious attention to muscular exercise a necessity for the modern man, especially the city-dweller.

Citarin, a Remedy against Gout.—Citarin is a white, fine crystalline powder, easily soluble in water, the solution tasting somewhat like lemonade. It is made by the action of formaldehyd on sodium citrate. A. Leibholz³ has employed it in doses of 2 gm. (30 gr.) in a number of cases of approaching gout. He gives it as soon as the first signs of the disease are manifest, giving 4 doses the first day and 3 doses daily for several days afterward. In every case the result was prompt, and in several it actually aborted the condition. Its advantages over colchicum are its nontoxicity, and therefore the possibility of taking large doses without unpleasant after-effects. Several times slight diarrhea was noted after it. It may in some cases be combined with aspirin. [E.L.]

Manipulative Correction of Congenital Torticollis.—

H. A. Wilson² states that when the unnatural posture of the head is caused by a contracture of the sternocleidomastoid muscle of one side, this being the most frequent form, it may be corrected by forcible manipulations. The method is applicable only to children under 7 years of age. In older patients the muscles are too resistant to tear without considerable risk of serious injury to the surrounding tissues. The patient is placed on a suitable table in the recumbent position and anesthetized. The operator grasps the head between his hands and turns the head so that the chin will point toward the shoulder of the affected side, rendering the muscle of that side tense. Additional corrective force will usually cause the contracted muscles to elongate. If this does not occur, the operator holds the head in the best possible position, as determined by the previous manipulations, while using forcible massage upon the muscle near its clavicular attachment. When sufficient correction has been obtained, fixation is secured by the application of plaster-of-paris with the head in a somewhat over-corrected position. This plaster cap should embrace the head except the face, the neck and shoulders, with a portion running under the axillas. Three or 4 weeks are ordinarily sufficient to obtain union of the torn portions of the muscles, when the plaster cap may be removed. Developmental movements should be instituted to secure coordination of the muscles in their new relations.

Treatment of Septic Conditions with Collargol.—

Credé³ says when used before the brain and heart have lost their resisting powers, and before metastases have occurred, this soluble silver preparation a few hours after its injection into the blood, produces a decided improvement. The good effect lasts as long as there is silver present in the blood, sometimes 2 or 3 hours. The injection may be repeated as soon as the patient's condition becomes worse. From preparations used in his first experiments definitely known solutions could not be made, nor were they at all times chemically pure, but since the middle of this year he is able to obtain a preparation of collargol chemically pure, and from which he can make known solutions. By using a strong solution the syringe can be sterilized. Now he uses a 2% solution, and injects half the amount (2 cc. to 10 cc.) of the former 1% solution. When he operates in septic cases he gives infusion of collargol instead of salt solution. The diseases in which this preparation was used embraced severe phlegmon and gangrene, general sepsis, peritonitis, erythema nodosum, anthrax, and hopeless cases of tuberculosis. In some of the cases that appeared to him hopeless, recovery ensued. In some of the tuberculous cases there was a decided improvement for several weeks. [A.B.C.]

Changes in the Medical Corps of the U. S. Army for the week ended March 5, 1904:

LA GARDE, Major LOUIS A., surgeon, is relieved from duty at Washington, D. C., and will proceed to San Francisco, Cal., and report for transportation to the Philippine Islands.

BOURKE, First Lieutenant JAMES, assistant surgeon, is relieved from temporary duty as attending surgeon and examiner of recruits in Chicago, Ill., and will proceed to Fort Sheridan for duty.

KILBOURNE, Lieutenant-Colonel HENRY S., deputy surgeon-general, will proceed to Iloilo, Panay, reporting to the commanding general, department of the Visayas, for assignment to duty as chief surgeon of that department, relieving Colonel John D. Hall, assistant surgeon-general, who will proceed to Manila, P. I., reporting to the commanding general, department of Luzon, for assignment to duty as chief surgeon of that department.

PATTON, First Lieutenant IRVINE W., assistant surgeon, orders of February 23 are revoked.

BINGHAM, First Lieutenant ERNEST G., assistant surgeon, is granted leave for ten days from February 22.

JORDAN, EDWARD H., contract surgeon, leave granted February 6 is extended one month.

YEAGER, CLARENCE E., sergeant first class, Fort McDowell, will proceed to the general hospital, Fort Bayard, for duty.

VOORHIES, HUGH G., contract dental surgeon, is assigned to duty at Fort Hancock.

MCCULLOUGH, E. A., contract surgeon, leave granted is extended one month.

ADAIR, Lieutenant-Colonel GEORGE W., deputy surgeon-general, will proceed to Fort Harrison for the purpose of making a thorough personal examination of certain property near that post offered for sale to the government, with a view to ascertaining its desirability as a sanatorium, etc. He will submit a report, giving the detailed information called for in the instructions referred to above, which were transmitted to him by endorsement.

Changes in the Medical Corps of the U. S. Navy for the week ended March 5, 1904:

SPRATLING, L. W., surgeon, ordered to report for special temporary duty in the Bureau of Medicine and Surgery, Navy Department—February 26.

DEVRIES, J. C., acting assistant surgeon, detached from duty with recruiting party No. 2, and ordered to Recruiting Station, Baltimore, Md.—February 26.

JANNEY, W. H., acting assistant surgeon, detached from Naval Recruiting Station, Baltimore, Md., and ordered to duty with recruiting party, No. 2—February 26.

TAYLOR, J. S., passed assistant surgeon, detached from Naval Hospital, N. Y., and ordered to accompany Marine Battalion to San Francisco, Cal., and thence to U. S. S. Relief—February 29.

MCCULLOUGH, F. E., passed assistant surgeon, ordered to Asiatic Station, sailing about March 9—February 29.

STRINE, H. F., assistant surgeon, detached from Naval Station, Olongapo, P. I., and ordered to U. S. S. Annapolis—March 2.

MURPHY, J. F., assistant surgeon, detached from U. S. S. Wisconsin and ordered to the U. S. S. Isla de Cuba—March 2.

Changes in the Public Health and Marine-Hospital Service for the week ended March 3, 1904:

NYDEGGER, J. A., passed assistant surgeon, granted leave of absence for one month from March 6, 1904, on account of sickness—March 2, 1904.

MC MULLEN, JOHN, passed assistant surgeon, bureau order of December 3, 1903, relieving Passed Assistant Surgeon McMullen from duty at Hongkong, China, and directing him to proceed to San Francisco, Cal., amended so that he shall report to the chief quarantine officer at Honolulu for temporary duty—February 29, 1904.

FRICKS, L. D., passed assistant surgeon, relieved from duty at the Immigration Depot, New York, N. Y., and assigned to duty in the office of the United States Consul at LaGuayra, Venezuela—February 29, 1904.

GOLDBERG, JOS., assistant surgeon, to report to chairman of Board of Examiners at Washington, D. C., March 9, 1904, for examination to determine his fitness for promotion to the grade of passed assistant surgeon—February 29, 1904.

KORN, W. A., assistant surgeon, to proceed to Washington, D. C., and report to chairman of Board of Examiners, March 9, 1904, for examination to determine his fitness for promotion to the grade of passed assistant surgeon—February 29, 1904.

HOLT, J. M., assistant surgeon, to proceed to San Francisco, Cal.—February 29, 1904.

TROTTER, F. E., assistant surgeon, relieved from duty at San Francisco, Cal., and directed to report to Passed Assistant Surgeon Rupert Blue, Plague Laboratory, San Francisco, for duty—February 26, 1904.

LLOYD, B. J., assistant surgeon, relieved from duty at San Francisco, Cal., and assigned to duty in the office of the United States Consul at Callao, Peru, February 26, 1904. To proceed to Concord, Cal., for special temporary duty—March 1, 1904.

BOGDANS, J. S., assistant surgeon, granted leave of absence for three days from February 18—March 2, 1904.

WARREN, B. S., assistant surgeon, granted one day's extension of leave of absence—February 22, 1904.

MANNING, H. M., assistant surgeon, relieved from duty at Honolulu, T. H., and directed to proceed to Manila, P. I., and report to chief quarantine officer for assignment to duty—February 29, 1904.

ASHFORD, F. A., assistant surgeon, granted leave of absence for ten days from March 28—March 1, 1904.

RICHARDSON, S. W., pharmacist, to proceed to St. Louis, Mo., and assume charge of the Marine-Hospital exhibit at the Louisiana Purchase Exposition—February 26, 1904.

Promotion.

Passed Assistant Surgeon J. C. Perry commissioned as surgeon—March 1, 1904.

Boards Convened.

Board convened to meet at Washington, D. C., February 29, 1904, for the physical examination of candidates for position of second assistant engineer, Revenue Cutter Service. Detail for the board: Assistant Surgeon-General L. L. Williams, chairman; Assistant Surgeon A. J. McLaughlin, recorder.

Board convened to meet at Washington, D. C., March 4, 1904, for the physical examination of Chief Engineer G. B. Maher, Revenue Cutter Service. Detail for the Board: Assistant Surgeon-General L. L. Williams, chairman; Assistant Surgeon-General W. J. Pettus, recorder.

Casualty.

Assistant Surgeon H. C. Russell died at Stapleton, N. Y., March 2, 1904.

PUBLISHED WEEKLY AT 1321 WALNUT STREET PHILADELPHIA BY THE AMERICAN-MEDICINE PUBLISHING COMPANY

VOL. VII, No. 12.

MARCH 19, 1904.

\$5.00 YEARLY.

Railway Car Hospitals have been ordered by the Pennsylvania Railroad for the purpose of being sent to scenes of accidents and wrecks. It is strange that this has not been done long before, since apart from the evident humanity of the project, it is clearly in the line of self-interest. Life and death often depend on the promptness of medical or surgical attention, and the difference between life and death, admittedly considerable to the sufferer, is readily translatable into dollars in the case of a company liable for damages. The example thus set by one of the model railways of the country should at once be followed by other companies, which in reality have more need of such a system. Fitted with all the modern and scientific devices and materials for the treatment of the wounded, stationed at convenient points along the lines of busy thoroughfares, under the instant command of the company's surgeons, these rolling emergency hospitals would be of the greatest service to the community. This is especially true in our country, where the loss of life by railway wrecks is much greater than in any other. The recklessness of life shown by our transportation companies demands at least this recompense, and they may at any time lessen the expense of the hospital service by greater solicitude as to the avoidance of preventable accidents.

Modern revivals of heathenism—such, literally, are many of the outbreaks of crazy fadism we are daily witnessing. It may not be wise, or at least possible, to repress them by law until overtly illegal barbarism is manifest, but these insane people are so expert in hiding their crimes, or in apparently keeping within certain extremes, that conviction is often difficult. The noteworthy feature of all these wild-eyed enthusiasts is the utter disregard, and even hatred, of the laws of hygiene and scientific medicine. This characteristic of the eddyites, faith curists, and similar insanities of a hundred types, gives warrant to the community and the law for interference when the young, innocent, and beguiled are sacrificed to the frenzy of unrestrained morbid-mindedness. From Maine come reports of people with strange delusions and manias which show the fury of the hidden fires of savagery beneath the thin lava crust of civilization. The "Holiness Society," for instance, at Beal's Island, near Jonesport, Me., according to report, was prevented by the sheriff from sacrificing children and from the murder of a family. The whole popula-

tion, with a few exceptions, appears to have become insane over the new cult brought to the island by the Holiness Society. The creed requires converts to impoverish and humiliate themselves, giving all their money to the ministers as the representatives of God, and casting away all other valuables. The leaders seemed to possess a hypnotic influence over the 300 islanders.

Failure in cancer research is the lamentable result bemoaned in all countries, and by all investigators. Although "certainly discovered" a score of times, the pathogenic organism and the pathogeny are as elusive as ever. At a recent meeting of the directors of the London Cancer Hospital, Dr. Herbert Snow, the senior surgeon, said that he and his associates had studied the disease as, to the best of his knowledge, it had been studied nowhere else in the world. They had attacked its problems with the microscope in one hand and the scalpel or the stethoscope in the other. They had labored by every means in their power to substitute for the mass of chaotic confusion and traditional fallacy which had hitherto prevailed—a genuine and precise cancer-science, as a sure foundation for all future research. And in this attempt they had failed—utterly and miserably failed. And now on all hands they found schemes of cancer research. Those also must fail—must of necessity fail—until some step was taken to clear away all the traditional lumber of past centuries and to formulate precisely what was known with certainty, what was known only imperfectly, and what yet remained to be ascertained. Cancer is not one but many diseases, as it includes ten genera and thirteen species. Each variety is established by a different cause or chain of causes. Each probably required a separate line of research. He had long thought that proper scientific investigation of the physiologic reasons for those remarkable diversities, referring mostly to the action of the lymph-glands on the cancer protoplasm, would assuredly far advance the practical knowledge of cancer, and might even lead up eventually to the ideal nonsurgical cure. But he heard no rumor of any such contemplated investigation. At present all was groping in the dark—or little more. Is there, then, something wrong with the methods of research of the pathologists? Has there been too great reliance upon bacteriologic and laboratory ways, and too little upon clinical and physiologic observations? It seems as if some obscure country practitioner stands as

good a chance to solve the enigma as the most famed and erudite. Perhaps the bacillus is not after all the arbiter of health and destiny.

Fraudulent Citations and Testimonials.—The parasitic scamps who infest the body of the medical profession well know how difficult it is to examine the files of a medical journal, and in fraudulently quoting they are careful not to give the dates, which would enable one to catch the cheat. It thus comes about that quotations and testimonials lauding some drug, book, or institution, and said to be taken from good writers and journals, may not be trusted any more than those appearing with portraits in the advertising columns of newspapers. The latter, as is well known, have a definite market price and are bought and sold exactly as any article of trade. Those of Mrs. Brown are cheap; those of policemen are somewhat higher, and quotations run higher and higher according as one is governor or congressman. These suggestions are made because of the testimonial quoted by the publisher of a book called *Dollars to Doctors*, said to be taken from *American Medicine*. The author of the book is a certain Wood of "St. Luke's Hospital," and "Christian Hospital" fame. The quotation is as follows:

"This is a neat volume of 272 pages, filled with wise and timely advice on the much neglected subject of success in practice. It is a work of great value to the general practitioner. The Lion Publishing Co., Chicago; \$2."

American Medicine never said it.

A demonstration of the curability of incipient pulmonary tuberculosis, is furnished in the report (1902-1903) of the Muskoka Cottage Sanitarium of Canada. Of 115 patients who remained at the institution over one month there were:

Discharged, apparently cured	24	=	20.9%
" with disease arrested	41	=	35.6%
" with marked improvement	30	=	26.1%
" unimproved	17	=	14.8%
" failed	3	=	2.6%
Died	0	=	0.0%
	115		100.00%

The report emphasizes the sharp distinction which is to be made between the curability of incipient and advanced cases; 75% or over of incipient cases may be cured, while of advanced cases we may look for less than 15% of cures, and of far-advanced cases barely 1%. This but emphasizes the necessity of taking the disease in its early stages and of not waiting till the symptoms become pronounced. During the year the real aim of this institution, the cure of incipient pulmonary tuberculosis, was again made subservient to the great need of the public. It cared for many patients far more advanced than the class intended to be treated there. Seventy-five percent of all patients admitted were classified as advanced cases. The results therefore must be considered not in a general percentage but in reference to the class of cases admitted. Of patients remaining longer than a month only 18% of those classified as advanced were arrested, though an additional 30% were very much improved, whereas, of the undoubtedly tuberculous cases classed as incipient, 82% were apparently cured or arrested. Such results must encourage all those who have been working for the establishment of sanitariums, and should bring definite

determinations with the charitable, and votes in legislative halls.

The premature burial bogey springs up periodically and persistently. The latest resuscitation of this long dead subject is a bill introduced into the Massachusetts Legislature with a fearful array of punishments and \$1,000 fines promised breakers who shall violate its provisions as regards notification, and putting corpses in coffins which exclude light, air, and movement, until certain tests of death shall have been made. These tests are in part as follows:

1. Heart-sounds entirely absent, the test being by the stethoscope.
2. Respiratory sounds entirely absent.
3. Temperature of the mouth same as that of surrounding air.
4. A bright needle plunged into the body of the biceps muscle, left there, shows no sign of oxidation.
5. Intermittent shocks of electricity at different tensions passed by needles into various muscles and groups of muscles give no indication whatever of irritability.
6. Fillet test applied to veins of the arm causes no filling of veins on distal side of fillet.
7. Opening of vein shows the blood to have undergone coagulation.
8. Subcutaneous injection of ammonia causes a dirty brown stain indicative of dissolution.
9. Careful movements of the lower jaw and of lower extremities and of occipitofrontalis indicates the presence of rigor mortis.
10. Scarlet line (diaphanous test) is absent.
11. Decomposition has set in. And provided, further, that, if there is an absence of any of the signs of death except decomposition, all known means of resuscitation shall be tried while such signs are absent.

The facts, as we have often pointed out, upon which the scare is based, are themselves most "diaphanous." Investigation of the newspaper reports of premature burials always shows them to be even more newspaperish than the usual newspaper "science." If carried out in the United States the expense to the people would run to many million dollars.

The professor lectures the Bowery, and in doing so, illustrates a doubtful medical and philologic science. His subject was "Hypno and Auto Suggestion," and was devoted to the thesis that the drink habit is controllable by suggestive therapeutics. The patient is tactfully conducted into the desired state of mind—or lack of it—and is assured that, in accordance with his own desire and decree, he has lost all craving for beer, wine, and whisky—that alcohol in any form will disgust him, and, as a safeguard, that he cannot swallow it, cannot carry the containing glass to his lips. Of 200 patients treated in this way by the speaker, 80%, he said, was saved. Now, "auto suggestion," he added, "is open to every one of you, and it will ennoble and beautify your lives. The state of mental abstraction called reverie, immediately preceding natural sleep, is most appropriate for treatment by this kind of suggestibility. As you are yielding to slumber, say to yourself that you will no longer be a slave of the dominant idea or the evil habit that is crippling your best expression." With a thousand earnest preachers of these glad tidings our country could in 10 years, he thought, be regenerated. The trouble, of course, is to get the thousand earnest preachers and practitioners of suggestion, auto or hypno. Then is not 80% a very high proportion of cures, even by any or all methods? Lastly, how about the failures? If suggestion is ineffective, will not the reaction be all the greater toward alcoholism? There are thousands of suggesters

to drink to one for abstention, and if suggestion is effective, *per se*, and to be indulged and encouraged, will not the stronger and more numerous forces conquer the weaker and fewer? We have perfect sympathy with every promising agency against the liquor habit, but as to the professor's plan we have the sincerest doubts. He introduces two words into the language both of the Bowery and of the educated world. These two coinages are *auto* and *hypno*. As component parts of other English words, we can guess at their meaning, but physicians have never treated patients with those articles of the *materia medica* called *auto* and *hypno*.

Some of the Trials of a Medical Journalist.—

One of our subscribers sends us the following letter, addressed to him by the editor of a medical journal:

DEAR DOCTOR:—We would like so much to have you write an article for our journal. At this time, when every doctor knows the effect of —, which has been used with so much success for many years past, a few clinical cases would be in order. Suppose you prepare six clinical cases. Simply outline the cases by giving sex, age, married or single, temperament, habits, mention any peculiarities of the patient, sometimes the statement of the patient himself makes interesting matter, and then give treatment, showing the results from — in each case. We would prefer, if possible, for you to report all cases of the same disease. If you are too busy to write the article as you would like, simply outline the cases as described above, and we will touch them up for you so as to give the proper tone. We know that physicians have long hours to work and we do not want to burden you with more work unless you can do it at your convenience and do it cheerfully. We are offering a clinical thermometer and our journal for one year for \$2, to induce new subscribers to take our journal. Should you have use for one of these thermometers, we will be pleased to send you one free with our compliments, and also send you our journal for one year. Please let us know how soon we can expect the article. Awaiting your reply, we beg to remain,
Very truly yours,

The condition of mind and of pocket book of the poor man who wrote this letter is pathetic, and commands sympathy; not so, however, the condition of the medical journalism which is neither journalistic nor medical; when it comes to the profession that permits or supports all of this, sympathy and wonder become simply disgust.

Should the General Practitioner Fit Himself to do Specialty-work?—The publisher of a medical book lately issued from his press, sends out a notice concerning the book, parts of which read as follows:

A Fee is as Good in the Pocket of the Practitioner as in that of the Specialist.

In these days when medical competition is so keen, it is not to be imagined that the general practitioner is lying awake at night devising schemes for turning over this or that patient to his brother, the specialist. He is rather devising ways and means by which he can treat the patient himself and retain the fee to which, by reason of his long and patient study of the case and devotion to his patient's interest, he is justly entitled. It has been so much the fashion of recent years to refer the patient suffering from kidney trouble to the specialist of renal diseases; the one suffering from throat trouble to the specialist of nose and throat disease; and the one suffering from eye-strain to the oculist, etc., that the field of the practitioner grows limited, unless by a little patient study and investigation and a small amount of capital he will post himself in all departments of medicine and keep fully abreast of the time, thereby fitting himself to treat such cases with justice to his patient and credit and profit to himself.

Is there a competent and reputable general physician who will agree to this? Certainly no specialist will do so. If it is possible, which we doubt, for the general physician to keep in the front of progress as regards the advances in general and internal medicine, and at the same time to acquire the requisite skill and knowledge to practise one or two of the more clearly defined specialties, it is not possible for him to do so in all the specialties. That is rank nonsense. The appeal to cupidity and superficiality, if not to quackery, in the above quotations is contemptible. It is fast becoming impossible for any general physician to be a master in his proper and chosen work and also in any one of the specialties. It is not to the advantage of the patient or of the profession that he should attempt it. He can at best acquire only such knowledge of the principal specialties as will enable him to know when to refer his cases to specialists. Let him do that conscientiously, quickly, and frankly, and he will still have enough to do. Especially if he demands, as he should, the equally important reference by the specialist of cases in general medicine back to the general physician.

Antipathies: Floral and Olfactory.—Antipathies and aversions rank among the most unreasoning and unmodifiable of the many contradictory features which occasionally bubble up from the depths to ruffle the surface of the placid mirror of the human understanding. One of the most remarkable and least explicable of the recorded antipathies is that connected with the rose—one of the most beautiful of flowers and sweet-smelling of odors—to the optical and olfactory organs of the ordinary civilized individual. Many very striking instances have been from time to time recorded, and on the most reliable testimony. Lady Heneage, of the Bed-chamber of England's "Good Queen Bess," had, we are assured by Sir Kenelm Digby, had her cheek severely blistered by having a rose surreptitiously placed thereon during sleep. We are told by the celebrated Amatus Lusitanus that there was a noble Venetian (a member of the Barbarigi family) who always fainted at the sight and smell of a rose, even at a distance; so that he was obliged to remain confined to his house during the annual period of the bloom of the rosebeds. Cardinal Don Henrique a Cardona always fainted when the smell of a rose reached him, even if not in sight. And another church dignitary, Laurentius, Bishop of Vratislavia, met his death by an attack of syncope brought on by the odor of roses. Cardinal Oliverius Caraffa also suffered from the same infirmity, and during the rose season shut himself up in his chamber, while care was taken that nobody bearing a rose was allowed to approach the palace. And the famous physician, Zacchias, a great medicolegal authority in his day, tells us that he himself was most unpleasantly affected by the odor of white roses, which always made his head ache violently, although he really liked the smell at the time. Johannes Quercitanus, secretary to Francis I, King of France, had a horror of the odor of apple blossoms and apples. If one of the latter were held near his nose, epistaxis always followed; and when there were any apples at table, he always stuffed his nostrils with bread crumbs. The odor of roses has frequently been found to produce epistaxis. A relative of

the famous Scaliger was thrown into a state of syncope by the smell or even sight of a lily. Magnolias have produced extreme nausea; and Dr. Barton has known their odor to produce an exacerbation of acute gout. Rue, carnation, orange, saffron, and peony have also excited extreme antipathies. The greatest proportion of floral aversions has, curiously enough, been reported from the sunny land of Italy, where the country people regard the introduction of perfumes into the lying-in-chamber as a fatal proceeding.

Antipathies: Digestive, Gustatory.—We are told by the famous physician and naturalist, Brassavolus, that the younger daughter of the King of Naples, who had been a patient of his own, could not bear to eat—or even taste—any flesh of any kind whatsoever; whenever she was induced to put a small morsel in her mouth she immediately fell to the earth, and rolled about shrieking and moaning for about half an hour. The celebrated physician and botanist, Guaianerius, has reported of himself that “hog’s flesh was so very great an enemy to him, that it produced the same accidents in him that poyson would have done, although he used but any part of it in sawces; as also that when his mother (who was desirous to accustom her son to all kinds of meats) had prepared for him (without his knowledge) a dish of that flesh, minced into smallest bits, and offered it to him to eat; within an hour after he fell into a palpitation of the heart, and thence into a *Syncope*, and thence into a vomiting, in which he brought up pure blood; so that they looked for no life in him.” And Felix Plater has recorded a similar aversion to meats of all kind, in a French boy, who “tabled with my father;” and who lived upon bread, fruits, and milk—the latter always cold. “In the meantime he was of good habit of body, fresh and well-colored.” Horstius has narrated the case of a “Noble Countess” whose lips always suddenly swelled whenever she tasted udder of beef—although she felt no actual dislike to that dish. Schenck mentions the case of a citizen of Antwerp, who immediately swooned off whenever hog’s flesh was placed on any table at which he was seated. The presence of eel—even enclosed in a paste—had the same effect in a case recorded by Henricus ab Heers. Amatus Lusitanus has recorded the case of a Spaniard of Toledo, who could never bear the taste of fish; so that when once given him, “well prepared and wrapped up in eggs, he immediately fell into fainting pressures of the heart, accompanied with vomitings and seige, so that little wanted but that he had dyed.” On the other hand, Donatus tells us of the son of a Count, who on tasting of egg, “his lips would swell, in his face would rise purple and black spots, and he would froth at mouth, after the same manner as if he had swallowed poyson.” And Schenck tells us of two other extraordinary cases of such aversion. One was that of a Norman rustic, who could never taste bread, flesh, or fish, but lived upon eggs, on which account he was called “the weasel.” The other was a Flanders maiden, who (then aged 16) had always lived upon milk. If even a small piece of bread were put into the latter she would detect it, even at a distance, by the smell.

BOOK REVIEWS

A Manual of Operative Surgery.—By SIR FREDERICK TREVES, Bart., K.C.V.O., C.B., LL.D., F.R.C.S. New edition, revised by the author and Jonathan Hutchins, Jr., F.R.C.S. In 2 Vols., Vol. No. II. Published by Lea Brothers & Co., Philadelphia and New York.

A review of the first volume of this work has already appeared in these columns. The second volume has now appeared, and it meets every expectation. The following subjects are discussed in the present volume: Plastic surgery, operations on the neck, operations upon the abdomen, operations on hernia, operations upon the bladder, operations upon the scrotum and penis, operations upon the rectum, operations upon the head and spine, and operations on the thorax and breast. It is difficult to select a portion of this excellent work which is more creditable than another. In view, however, of the rapid evolution in plastic surgery, it is particularly interesting to find in the work before us such an excellent dissertation upon this subject. The numerous illustrations throughout the work add special value. The parts devoted to hernia, hemorrhages, various operations upon the intestines, the kidney, and the bladder, are particularly interesting and instructive. The method of procedure in the numerous operations presented throughout the work are described somewhat tersely, clearly, and in that explicit and direct manner to be expected from one who has achieved such success in the profession. A special feature in connection with the various operations is the after-treatment, which, in the vast majority of surgical works, is passed over with scant attention. The 2 volumes as now completed, are excellent from every standpoint. The publishers are to be commended for the excellent style of these volumes, the quality of paper, the printing, the cuts and binding, all of which are excellent in their execution and complete in detail.

The Treatment of Fractures, with Notes Upon a Few Common Dislocations.—By CHARLES LOCKE SCUDDER. Fourth Edition, thoroughly revised. Published by W. B. Saunders & Co., Philadelphia, New York, and London.

The fact that the fourth edition of this valuable work has appeared in less than 4 years from the appearance of the first edition is sufficient guarantee that the author has kept entirely abreast of the latest discoveries, means of diagnosis and methods of treatment of which the profession have become possessed. The elaborate series of illustrations, comprising some 688, give the student and practitioner a mental picture of almost every fracture that is likely to take place in the human body. This, together with the methods of diagnosis and the efficient means of treatment, whose application is splendidly illustrated in many cases, comprise the volume. A number of röntgen illustrations are presented in the present edition, which, taken all in all comprise an exceedingly valuable addition to surgical literature as applied to fractures and many of the more common dislocations.

Prostatic Hypertrophy from every Surgical Standpoint.—By GEORGE M. PHILLIPS, M.D., and 40 distinguished authorities. Edited and compiled by S. C. Martin, M.D. Published by Lewis S. Matthews & Co., St. Louis, Mo.

This is a very readable book of nearly 200 pages and consists of the expressed opinions of the distinguished authorities on the subject under consideration. These authorities have written answers to 14 questions propounded by the author, the questions being such as these: 1. To what extent does occupation tend to prostatic hypertrophy? Answer with special reference to active indoor, active outdoor and sedentary pursuits. 3. In brief, what is the etiology of prostatic hypertrophy? 6. In what cases do you advise palliation and of what does this consist. 10. How often have you practised suprapubic drainage and what is your estimate of results? Likewise are asked questions pertaining to suprapubic and perineal prostatectomy, complications, the result of cystoscopic examination, etc. These answers are published as given and enable the reader to view the answers from many different lights, according to the views and experience of the various authorities. In view of the revived interest in connection with prostatic hypertrophy

and the evolutionary condition of treatment as applied to this malady, the little book forms an interesting and instructive volume.

The New International Encyclopedia. Volume XIV.—Dodd, Mead & Co., New York.

This number runs from Philadelphia to Rice-bird. Among the medical and semimedical articles included are:

Phlebitis	Ptosia
Phlegmasia alba dolens	Puberty
Phosphatic diathesis	Puerperal fever
Phosphorus	Puerperal insanity
Phototherapy	Pulse
Physical training	Purgatives
Phytolacca	Purpura
Picrotoxin	Pyemia
Piles	Quarantine
Pill	Quassia
Pink eye	Quinin
Pin worm	Quinsy
Piperazin	Radioactivity
Pityriasis	Radium
Placenta	Rectum, Diseases of
Plague	Relapsing fever
Plasters	Remittent fever
Pleurisy	Resection
Pleurodynia	Resins
Pneumonia	Resorcin
Podophyllum	Respiration, Artificial
Poisonous plants	Respiratory sounds
Potassium	Rest cure
Pott's Disease	Resuscitation
Prescription	Retention of urine
Prolapsus ani	Retinitis
Prolapsus uteri	Rheumatism
Prostate gland	Rhinitis
Prurigo	Rhinoplastic operation
Psoriasis	Rhubarb
Psoriansis	Rib, Fractures of
Ptomains	

The following subjects, several of them of first importance, are either not treated or are without cross reference:

Photomicrography	Pterygium
Pica	Pyelitis
Plaster-of-paris (surgical uses)	Pyrogallol
Plastic surgery	Quebracho
Plethora	Railway injuries
Pneumonokoniosis	Raynaud's Disease
Pneumothorax	Rectocele
Postpartum hemorrhage	Reflexes
Protargol	Resinol
Prunus Virginian	Retinoscopy
Pruritus	

P, Q and R seem to be unfortunate initials for members of the medical profession, less than half the usual quota of famous names being chronicled, such familiar ones as Raynaud, Pinard, Pirogoff, Porro, Rasmussen, Reichman, and Reusner being omitted. The majority of the articles are quite short, the longer ones for the most part dealing with subjects that have achieved medical interest comparatively recently, as, for instance, those on radioactivity, phototherapy, etc. The nervous reflexes and their elicitation, so important from a diagnostic standpoint, are not mentioned; refraction, including retinoscopy, as a department of ophthalmology, is not alluded to. The articles are all readable and exhibit the usual intelligent conservatism. The work as a whole has been exceptionally free from typographic errors. An unimportant one occurs on page 543, where proctus is substituted for procedure at the top.

International Clinics.—Volume IV. Thirteenth series, 1904. Edited by A. O. J. KELLY, A.M., M.D. Philadelphia: J. B. Lippincott Company.

This, the concluding volume, is in some respects the best of the thirteenth series. It contains a large number of readable short articles, no less than 28 being included in the 304 pages of text, grouped under the headings of Treatment, Medicine, Surgery, Gynecology and Obstetrics, Neurology, Orthopedics, Ophthalmology and Pathology. Among the names in the list of contributors are Albarran, DaCosta, Duckworth, Julien, Keen, McFarland, Musser, Poynton, Senn, Tyson, and Wiggin. Space forbids mention of the long list of contents, which includes a wide range under the topics given. The tendency to increase the number rather than the length of the articles is to be commended.

The Treatment of Neurasthenia.—By A. PROUST and G. BALLET. Translated by Peter Campbell Smith, M.D. E. R. Pelton, New York, 1903.

This small book of less than 200 pages contains many helpful suggestions regarding the treatment of the troublesome affection in question. Conciseness and clearness are valuable features of the work. The rest treatment of Weir Mitchell is largely used as a basis in ordinary cases. Before definitely considering treatment, the authors devote some space to the nature, causes, symptoms and clinical forms, and the prophylaxis of neurasthenia.

The Self-cure of Consumption without Medicine.—By C. H. S. DAVIS, M.B. E. B. Treat & Co., New York, 1904.

This book of 160 pages is largely a compilation of well-known facts regarding the cause, transmission, prevention, and curability of pulmonary tuberculosis. Modern principles of treatment, including ventilation, breathing exercises, diet, exercise, sanatorium life, etc., are put in popular form without sacrifice of scientific truths. For this reason the book can be recommended as a source of knowledge that is proper to be put into the hands of the tuberculous generally.

Anatomy Applied to Medicine and Surgery.—By D. E. MUNDELL, B.A., M.D. Published by E. R. Pelton, New York City.

This is a volume of 500 pages devoted to anatomy as applied to medicine and surgery, particularly the latter. The arrangement of the book is rare, unique, and in many respects meritorious. Various regions of the body are taken up under separate headings and the anatomic description of the part given, together with the landmarks, functions, and the various pathologic conditions which may arise in the part, together with such treatment as the varying conditions would indicate. As an example we might cite the heading, region of the elbow, under this are the subheadings anatomy, phlebotomy, bursa, elbow-joint, fractures, dislocations, excision. These are tersely and intelligently discussed. Thus the various anatomic regions of the body are taken up and discussed accordingly. As a practical book for ready reference for the busy practitioner we believe this book possesses very considerable merit.

A Compend of Diseases of the Skin.—By JAY F. SCHAMBERG, A.B., M.D. Third edition, revised and enlarged. Philadelphia: P. Blakiston's Son & Co., 1903.

This edition of Dr. Schamberg's Compend of Diseases of the Skin does not differ in any important particular from the second. A few additions and revisions have increased the usefulness of the book, which is a concise and reliable outline of the more important facts of dermatology. Conclusive proof that it has been found useful by the student is afforded by the fact that 3 editions have been called for.

Transactions of the National Association of the U. S. Pension Examining Surgeons. Volume I.—Published by the Association; Issued by the Burnett Publishing Co., Rochester, N. Y.

This is a volume of over 200 pages containing the papers presented at the Second Annual Meeting at Washington, D. C., May 13 and 14, 1903, together with discussions thereon. There is also included an account of the first meeting at Saratoga Springs, June 9, 1902. The articles are varied in character and presented by able men throughout the country and these, together with the discussions which were brought out when the papers were presented, comprise a valuable and readable book.

The Practical Medicine Series of Year Books. Vol. X. Skin and Venereal Diseases; Nervous and Mental Diseases.—Edited by W. L. BAUM, M.D., HUGH T. PATRICK, M.D., Chicago. The Year Book Publishers, 1903.

This small volume contains a fairly complete, although necessarily brief, review of the more important literature of skin and venereal diseases and nervous and mental diseases which has appeared during the year preceding its publication. The chief criticism we have to offer is that in the portion devoted to dermatology, no definite plan has been followed in

the arrangement of the subjects considered. The various diseases are taken up apparently haphazard; for example, we find a paragraph on cutaneous horn immediately preceded by one on varicella occurring on the conjunctiva, and followed by one on iodoform eruptions. The same criticism, however, does not apply to other sections of the volume, which seem to have been arranged upon a more definite plan. A full index adds materially to the usefulness of the volume.

The Blues.—By ALBERT ABRAMS, A.M., M.D., F.R.M.S. New York: E. B. Treat & Co., 1904. Price, \$1.50.

The object of this little volume is to direct attention to a variety of nerve exhaustion which the author states has been heretofore undescribed, and which he designates splanchnic neurasthenia. The characteristic symptoms are periods of depression popularly known as "the blues." Of the eight chapters in the book, the first 5 are devoted to general considerations on neurasthenia, including irritants as causes, symptoms, and general treatment. The last 3 chapters contain a discussion of the cause, symptoms, and treatment of splanchnic neurasthenia. The fundamental condition underlying this type of neurasthenia is congestion of the abdominal or splanchnic veins; this may be primary in origin or secondary to nervous exhaustion. Treatment must therefore be directed not only to the neurasthenia itself, but also to the local abdominal condition. Physical methods for relieving congestion of the abdominal veins are discussed under the following heads: 1. Massage of the abdominal wall. 2. Exercises that strengthen the abdominal muscles. 3. Respiratory exercises. 4. Electricity to the abdomen. 5. Abdominal supporters. 6. Cold water. An appendix contains numerous notes on the liver, lung, heart, and other reflexes. The book is very clearly written, and is an addition to the literature on the protean disease neurasthenia, that is worthy of a careful perusal.

Plain Hints for Busy Mothers.—By MARIANNA WHEELER. E. B. Treat & Co., New York, 1903.

This booklet of 54 pages contains many helpful suggestions for busy mothers who perhaps have several small children to care for and who must do without many of the conveniences or even the necessities of life. Directions are given for bathing, dressing, feeding, and training the child. While the incompleteness of all such books renders their value questionable, the points given in this particular instance are very practical.

The Acid Autointoxications.—By DR. CARL VON NOORDEN and DR. MOHR. Part IV in the series of Clinical Treatises on the Pathology and Therapy of Disorders of Metabolism and Nutrition. E. B. Treat & Co., New York, 1903.

We have had occasion to commend the previous volumes in this series and find the latest to be fully as valuable as the preceding. The subject is perhaps not quite so inviting, as stated by the editor, but is of considerable importance to the therapist. The conciseness of these monographs is particularly pleasing.

Mammalian Anatomy, with Special Reference to the Cat.—By ALVIN DAVISON, Ph.D. Philadelphia: P. Blakiston's Son & Co., 1903. Price, \$1.50.

For the student of zoology, and particularly the prospective medical student, we know of no better short work on mammalian anatomy than this one of Davison. The text is clear and explanatory and the illustrations, 108 in number, are excellent. The book contains 242 pages of text. Each subject is followed by a short list of suggestive questions to aid the student in review.

The Principles of Open-air Treatment of Tuberculosis and of Sanatorium Construction.—By ARTHUR RANSOME, M.D. London: Smith, Elder & Co., 1903.

The contents of this book of 104 pages are composed of 4 essays on, respectively, the principles of sanatorium and open-air treatment of pulmonary tuberculosis, certain bodily conditions resisting pulmonary tuberculosis, the principles of sanatorium construction, and the pure-air treatment of pulmonary tuberculosis at home. A diagram of plans and sections for a sanatorium is included. Ransome believes that the suc-

cess of sanatorium treatment may to some extent be explained by its blood-making power, a power which may need to be pushed beyond the limits of perfect health. In conclusion, he emphasizes a point that is too often overlooked by modern writers on the home treatment, or self treatment, of tuberculosis, namely, that all the details of successful home treatment cannot be carried out except under the constant supervision of a physician and a nurse, or competent attendant.

A Manual of Hygiene and Sanitation.—By SENECA EGGERT, A.M., M.D. Third edition, enlarged and thoroughly revised. Illustrated. Lea Brothers & Co., Philadelphia and New York.

This manual now contains 460 pages of useful information that has been brought down to date, and hence sets forth the most recent advances in the realms of sanitation. The author is an enthusiastic teacher of hygiene, and the reader of his book is impressed by the fact that it has been written for the purpose of inducing further study of the methods of preventing disease. It remains one of the very best of the smaller works on hygiene.

Electrodiagnosis.—By J. MONTGOMERY MOSHER, A.M., M.D. Albany, N. Y.: Brandow Printing Co., 1903. Price, \$1.

This scheme for the differential testing of nerves and muscles as an aid to diagnosis is one of the most practical of recent medical publications. A few pages are devoted to the technic of electrodiagnosis and the variations in electric excitability. The remainder of the little book gives the action of the various nerves, their motor points, and the motor points of the muscles supplied by them. Plates of the various regions of the body show the location of these points. The book is so concise, 55 pages, and so completely fulfils its purpose that it should be in the hands of every physician who in any way employs electricity.

BOOKS RECEIVED.

[Prompt acknowledgment of books received will be made in this column, and from time to time critical reviews will be made of those of interest to our readers.]

Die Fäces des Menschen.—By PROF. AD. SCHMIDT and DR. J. STRASBURGER. Part III. August Hirschwald, Berlin, 1903.

Infant Feeding in its Relation to Health and Disease: A Modern Book on all Methods of Feeding. For students, practitioners, and Nurses.—By LOUIS FISCHER, M.D., Visiting Physician to the Willard Parker and Riverside Hospitals, of New York City; Attending Physician to the Children's Service of the New York German Poliklinik; Former Instructor in Diseases of Children at the New York Postgraduate Medical School and Hospital; Fellow of the New York Academy of Medicine, etc. Third edition, thoroughly revised and largely rewritten. Containing 54 illustrations, with 24 charts and tables, mostly original. 357 pages. Neatly bound in extra cloth. Price, \$1.50, net. F. A. Davis Company, Publishers, Philadelphia, Pa.

Atlas of Anatomy for Students and General Practitioners.—By PROFESSOR CARL TOLDT, M.D., and K.K. HOFRATH, Senior Professor of Anatomy in Vienna. Only authorized English translation from the third German edition by M. EDEN PAUL, M.D. With wood-cuts (many in several colors) and explanatory text. The explanations are given in the English as well as in the International nomenclature, a circumstance which will recommend the work particularly to teachers and students. Complete in 6 volumes. Cloth bound, \$18.00.

A Manual of General Pathology for Students.—By SIDNEY MARTIN, M.D., F.R.S., F.R.C.P., Professor of Pathology at University College; Physician to University College Hospital, London. With numerous wood-cuts from microphotographs and other illustrations, including many in colors. P. Blakiston's Son & Co., Philadelphia, 1904. Price, \$4.00 net.

A System of Physiologic Therapeutics: A practical exposition of the methods other than drug-giving, useful for the prevention of disease and in the treatment of the sick.—Edited by SOLOMON SOLIS COHEN, A.M., M.D., Senior Assistant Professor of Clinical Medicine, Jefferson Medical College; Physician to the Jefferson Medical College Hospital, etc. Volume vii.

Mechanotherapy and Physical Education including Massage and Exercise.—By JOHN K. MITCHELL, M.D., Fellow of the College of Physicians of Philadelphia; Physician to the Philadelphia Orthopedic Hospital and Infirmary for Nervous Diseases; Assistant Neurologist to the Presbyterian Hospital of Philadelphia, etc. **Physical Education by Muscular Exercise.** By LUTHER HALSEY GULICK, M.D., Director of American Physical Training, Public Schools of Greater New York; President of American Physical Education Association, etc. Special articles have been contributed as follow:

Orthopedic Apparatus.—By JAMES K. YOUNG, M.D., Professor of Orthopedic Surgery in the Philadelphia Polyclinic; Clinical Professor of Orthopedic Surgery in the Women's Medical College of Pennsylvania, etc. **Corrective Manipulations in Orthopedic Surgery (Including the Lorenz Method).** By H. AUGUSTUS WILSON, A.M., M.D., Clinical Professor of Orthopedic Surgery in the Jefferson Medical College; Emeritus Professor of Orthopedic Surgery in the Philadelphia Polyclinic; Orthopedic Surgeon to the Philadelphia Hospital; Ex-president of the American Orthopedic Association, etc. **Physical Methods Employed in Ophthalmic Therapeutics.** By WALTER L. PYLE, M.D., Assistant Surgeon to the Wills Eye Hospital, Philadelphia. With 229 illustrations. P. Blakiston's Son & Co., Philadelphia, 1904.

AMERICAN NEWS AND NOTES.

GENERAL.

Ten Physicians in One Family.—In Lovington, Moultrie county, Ill., Dr. J. D. Donovan, who has practised medicine and surgery for 40 years, has raised 9 sons to adopt the same profession. Four are now in college, but 5 have practices of their own. The elder Donovan is a native of Marshall county, Ky., where he was born in 1836.

Red Cross Society.—If newspaper accounts are to be credited a difference of opinion exists between Clara Barton, president of the National Red Cross Association, and certain auxiliary bodies of that association. It appears the National Red Cross Association offered its services to the combatants at the seat of war in the far East; the offer was not accepted owing, it is asserted, to a possible fear that international complications might arise, and the further fact that the combatants were plentifully supplied with trained assistants in the armies; instead, the offer, particularly of the auxiliary body in Philadelphia, was accepted and nurses sent to the far East. The National Association feels that slight has been put upon it.

Tuberculous Patients Need not Go West.—Dr. Abraham Jacobi was the principal speaker recently at a mass meeting of East Side working people. He said that the spread of tuberculosis is preventable by the people themselves at little expense. The principal thing is attention to the ordinary sanitary laws and the rules of cleanliness. "Windows should be left open a little," he said, "not necessarily more than a little in cold weather. Baths should be taken frequently and people should stay as much in the open air as possible. Instead of long trips to Colorado, short trips to farms in the neighborhood of the city where the air is just as good will serve as well. There is plenty of pure, bracing air near the city which would have a wonderful tonic effect in the incipient stages of the disease."

Bequests to Charity.—Newport, R. I.: By the will of the late Miss Sarah Schermerhorn, the sum of \$200,000 was left to various institutions, among which was the Home for Consumptives, of Denver, Col., which received \$50,000; the New York Association for the Improvement of the Poor received \$15,000; the New York Institute for the Blind, \$5,000; Children's Aid Society, of New York, \$30,000.—Baltimore: By the will of the late George Brehm certain institutions were remembered as follows: To the president and directors of the General German Aged People's Home of Baltimore city, \$500; to the General German Orphan Association, \$500; to St. Anthony's Orphan Asylum of Baltimore city, \$1,000; to St. Joseph's German Hospital of Baltimore city, \$1,000.—Boston: By the will of Nathaniel A. Moody, to the Waltham Hospital is given all of the real estate and property left at the death of the testator's wife. The amount is estimated to be about \$12,000 or \$16,000.

Special Cars for Tuberculous Patients.—Tuberculous patients may be barred from first-class Pullman cars on the Santa Fe railway. The plan involves the running of hospital cars at intervals on through trains. These cars will be specially equipped, and no one except sick persons will be allowed to ride in them. This innovation in train operation will be put into effect between Chicago and Kansas City to Colorado and New Mexico health resorts, and to California points, over practically the entire system. The care of tuberculous patients has always been a burden to the railroads. After a berth has been occupied by a tuberculous patient it must remain unoccupied until the end of the run, when it is disinfected. This precaution for the care of the health of the traveling public involves expense. There is prejudice against riding in cars that are known to have been occupied by tuberculous patients. The hospital cars will probably be put in operation at the opening of the summer tourist business this season.—[*Daily Medical.*]

Profits on Patent Medicine.—According to the *Daily Medical*, the Utah State Board of Health is waging war against patent medicine manufacturers and vendors in that State. The secretary of the Board of Health has caused samples of various patent medicines to be bought from the shelves of druggists and submitted to the State chemist for examination. One alleged remedy, widely advertised as "Hyomei," a liquid preparation for catarrhal troubles, was found to be crude oil of eucalyptus diluted in oil of vaselin. The retail price printed on the label was \$1. Kauffman's Sulphur Bitters was another "remedy" for about 50 different ailments of a patient's insides. On the label was printed "No alcohol," but the State chemist found 23.4% of alcohol in the pint bottle which sold for \$1. Moreover, there was not even a trace of sulfur, and the alleged restorative had no curative properties that could be discovered. "Swamp Root" was a third "remedy" for all the ills the flesh is heir to—particularly in the line of renal troubles. The chemist found 9.6% of alcohol in the pint bottle, with a large percentage of sugar and juniper berry. "Paine's Celery Compound" was a fourth, a \$1 per pint "remedy." The analysis showed 20.9% of alcohol, as much as will be found in wine, and also the presence of a large amount of fusel oil. This makes it worse than straight whisky. But the chief of the collection was Birney's Catarrhal Powders. In this precious stuff

Chemist Harms found nearly 2% of cocaine, with 90% of sugar preparations and inert substances to hold the deadly drug. The preparation is sold in small vials, each containing 1.5 gr. of cocaine.

Decrease of Tuberculosis in Large Cities.—In the Maryland *Medical Journal* for February "The Statistical Laws of Tuberculosis" are discussed by Mr. Frederick L. Hoffman, who makes the gratifying announcement that "the mortality from tuberculosis has progressively declined in American cities for more than half a century." In New York, for example, the deathrate from tuberculosis per 10,000 of population was 42 during 1851-1860, against 27 during 1891-1900. In Boston the rate was 46 in the former years and 26 in the latter. Baltimore shows a like decline of the mortality from the white plague. In 1876-1880 the rate was for Baltimore 36 per 10,000 of population, and in the period 1896-1900 but 21. As these figures include the colored element, which is only partially amenable to sanitary regulations, a gratifying amelioration of the conditions affecting the prevalence of the disease among the people is indicated. There has been in all the principal American cities, according to the writer, "a progressive decrease in the mortality from this disease from decade to decade during the past 40 or 60 years." And this decrease antedates, he adds, by many years the discovery of the tuberculosis bacillus by Koch and the new view that the disease is highly infectious.

NEW YORK.

Typhoid Epidemic in Watertown.—Information from Watertown, N. Y., March 10, says: George A. Soper, of New York, the sanitary expert who is in charge of the typhoid fever situation here, says that there is a marked improvement in conditions. The number of cases reported daily shows a decided decrease, and the total number of cases is considerably less. The number of cases now in the city is less than 500. Arrangements have been practically completed for supplying the city with pure spring water. A number of tank wagons will be put into commission, and kept until the filtration plant is in operation next fall.

Infectious Pneumonia.—A New York exchange says: The increasing prevalence and deathrate of infectious pneumonia is recognized by the State Health Department in its monthly bulletin by the announcement that hereafter it will be given a separate column in the bulletin, and be the subject of distinct notice. Hitherto it has been grouped in the reports with other "acute respiratory diseases." The term will be used as including only acute lobar pneumonia, and not catarrhal or bronchopneumonia. The bulletin says: "While many prefixes to this name appear on our death returns, it is pretty safe to say that physicians generally understand the distinction as to the infectious disease we desire to specially record." The total number of deaths from pneumonia in the State during January is given as 1,510. This is more than half of the average mortality in the State for all acute respiratory diseases, including pneumonia, for 5 years.

New Colony for Insane in Northern New York.—In the annual report of the State Commission in Lunacy, the commission points out with considerable emphasis the necessity of beginning work at the earliest possible moment upon the proposed new colony for the insane in northern New York. The impending transfer to Kings county of the buildings now accommodating 1,200 insane, is referred to, and the commission points out the necessity of providing accommodations for these as well as the 3,800 additional patients who will require housing by the time the new colony is made ready. The commission renews its recommendation for the establishment of a reception hospital in New York City, designed for the immediate care and treatment of acute and curable cases of insanity; that arrangements be made at general hospitals in the larger cities and towns for the temporary detention of emergency cases, this provision supplanting the use of jails and station houses for this purpose; also, the establishment of so-called convalescent houses at a distance from the hospitals for patients not sufficiently recovered to return home, yet able to leave the institution.

Race Suicide in Middletown.—State Health Commissioner Dr. Daniel Lewis, formerly president of the State Board of Health, wants to know the cause of the extremely low birthrate for the city of Middletown, which, as he has noticed, hardly exceeds half the number of deaths. Race suicide has been suggested, but the members of the Board of Health say that as regards themselves this is not so. One of the members particularly refutes the statement by saying: "And on the seventh he rested." The fact of the matter is, however, the birthrate is far too low for a city of 15,000 population. In the past 5 years there have been only 757 births, while the death list foots up to 1,358. The marriages for the 5 years have been about half the deathrate. There is no visible reason why Middletown's birthrate should be so extremely low, as the population is strictly of the middle class, the proportion of wealthy citizens being very small. Of course, the proportion of very poor people, among whom births are most numerous, is also limited. The births and deathrate for the city for the last 5 years show that there were 100 births in 1899, 136 in 1900, 196 in 1901, 146 in 1902, 179 in 1903, as against 266 deaths in 1899, 331 in 1900, 267 in 1901, 246 in 1902, and 248 in 1903.

Arrested for Practising without being Registered.—On a warrant sworn out by 2 female detectives of the New York County Medical Society, charging him with practising medicine without being registered as a physician, Dr. Carl F. Starken, 44 years old, living in the Albany apartments, at 224 West Fifty-second street, was arrested recently by Policeman Buckley and arraigned in the West Side Court.—[*New York Times*.]

PHILADELPHIA, PENNSYLVANIA, ETC.

Lectures on Tuberculosis.—The fifth lecture in the International Course, given under the auspices of the Phipps Institute, will be delivered by Professor Maragliano, of Genoa, Italy, on Monday evening, March 28, at the Witherspoon Building, Philadelphia, the subject being "The Specific Therapy of Tuberculosis and Vaccination against the Disease." An invitation is extended to the medical profession.

Baby Weighs 24 Ounces.—The smallest baby ever born hereabouts was ushered into the world March 10 at the home of Mr. and Mrs. T. H. Keefer. The baby weighs only 24 ounces and is so tiny that it could be drowned in an ordinary tumbler filled with water. The babe is fully developed and is in excellent health. Baby's father is 5 feet 8 inches in height and weighs 209 pounds. The child's mother is of average height and weight.

Lorenz and Hoffa to Visit the United States.—Dr. Adolf Lorenz, of Vienna, who has formerly made several visits to the United States, and Prof. Dr. A. Hoffa, of Berlin, have both accepted invitations to hold clinics at the Jefferson Medical College Hospital, Philadelphia, in June of the present year. The date of the first clinics have been arranged for Monday morning, June 6, the day before the first session of the American Medical Association. The dates of other clinics will be announced later.

Morbidity and Mortality in Philadelphia.—There were 142 new cases of typhoid fever, with 25 deaths reported to the city health authorities, for the week ended March 11, as against 195 new cases, and 19 deaths for the week previous. Notwithstanding this, the health authorities are convinced that the marked decrease is only temporary, and the near future will probably see many new cases reported and a further extension of the disease. This belief is based upon the fact that the water-supply for many sections of the city is fearfully contaminated, and little short of horrible in character. Smallpox, which was thought to have run its course, broke out afresh in the early part of the week, and 48 new cases were reported, an increase of 15 new cases compared with the previous 7 days. Deaths from all causes numbered 700 last week. This is the largest number reported in any week for a year, and 81 more than for the week before. Of the deaths, 141 were due to pneumonia, which prevails in every ward in the city. There were also 12 deaths from grip.

Pennsylvania Medical Students Disappointed.—The medical students of Jefferson Medical College, the medical department of the University of Pennsylvania, and the Medico-Chirurgical School are disappointed, owing to a late ruling by the State Board of Medical Examiners of Pennsylvania. The board has decided that hereafter the certificate issued by the New York State Board will not be accepted in the State of Pennsylvania. This is particularly disappointing to prospective graduates, who heretofore could take the State Board examinations in New York and, having passed, could, by the payment of an additional fee of \$15, have their license accepted in both Pennsylvania and New Jersey. This is all the more disappointing owing to the fact that at the end of the sophomore year in the State of New York students are allowed to take examination in certain studies that have been completed by that time, and in the final examination the grades made at the end of 2 years are accepted without further examination. Since a number of students have taken these mid-grade examinations and expected to complete their examinations in New York, it is all the more disappointing to them.

SOUTHERN STATES.

Maryland Physicians Ask for \$50,000.—A large delegation of prominent Maryland physicians have asked the State Legislature for \$50,000 to erect a fireproof building for the custody of the library of the Medical and Chirurgical Faculty. The bill as introduced called for \$100,000, but the visitors state that in consideration of the many urgent claims upon the State at this time they would voluntarily reduce the amount to \$50,000.

Commission to Investigate Tuberculosis.—The Governor of Maryland is authorized to appoint a tuberculosis commission of 5 persons, 3 of whom shall be physicians, under the provisions of a bill recently introduced. The commission is to determine the relations of the disease to public health and welfare, and to devise means for restricting and controlling it. A report is to be made on the proper equipment and location of a sanatorium. The members of the commission are to serve without pay, and are empowered to fill any vacancy that may occur in the membership of the commission. In order to provide for the expenses of the commission, \$6,000 is set aside.

Mortality Rate in Baltimore.—The deathrate, as reported by the Health Department for the week ended March 12, is still high, but shows a considerable falling off from the preceding week. The total number of deaths reported for the week was 282, as against 231 for the corresponding week of last year. The deathrate in 1,000 population was: Whole, 26.82; white, 22.87; colored, 48.29. Of these deaths, 34 were due to pulmonary tuberculosis and 46 to pneumonia.

American Physicians Would Enlist in the Russian Service.—Recent information from Washington states that a large number of American physicians have offered their services to the Russian Government for hospital service during the war with Japan. It is stated that the Czar of Russia is grateful for the spirit of friendship thus manifested, but owing to the overwhelming number of physicians in his own domain, he has declined to accept the service of Americans.

Bill to Levy Penalty for Spitting.—A bill making it unlawful to expectorate on the floor, seats or platforms of passenger cars or steamboats has been recently introduced in the Maryland Legislature. It also forbids spitting in public buildings. The fine is \$3.50, half of which is paid to the informer. Justices of the Peace are given jurisdiction over all of such cases. Railroad and steamboat companies are required to provide cuspidors, and failure to do so subjects the companies to a fine of \$25.

War against Tuberculosis.—Bills have been lately introduced in the Maryland Legislature providing for the registration of tuberculous patients and to provide for the enactment of precautionary measures to prevent the spread of the disease. These bills were prepared by the State Tuberculosis Commission, acting in conjunction with the State Board of Health. They are explained in some detail by Dr. Fulton, secretary of the Board of Health. The registration bill authorizes the State Board of Health to request all physicians to report to the local Boards of Health all cases of laryngeal or pulmonary tuberculosis that are treated by them; and further authorizes the State Board of Health to keep a register of all such cases reported, the data thus secured to be available for statistical purposes, but otherwise to be regarded as absolutely private and confidential. If these measures become laws they will be operative throughout the entire State, including the city of Baltimore. The Health Department officials of Baltimore recognize the importance of disinfection and disinfect the premises that have been occupied by persons suffering from tuberculosis whenever asked to do so. But up to the present time they have not been able to require persons whose houses or apartments have been occupied by tuberculosis patients to fumigate the infected apartments, as they are able to do after rooms have been occupied by persons suffering from other contagious diseases, for the reason that there has been no law authorizing it. This law will give the necessary authority.

Instruction in Preventive Medicine at Columbian University.—It appears that the board of trustees of Columbian University have arranged that hereafter, if certain conditions in regard to endowment be met, the University will conduct a course in preventive medicine. Section 1 of the measure providing for such organization says: "That there shall be created in the University, as hereinafter provided, a department of civics, for the purpose of graduate education in the subjects of preventive medicine and the fundamental and administrative laws pertaining to the prevention of disease, epidemics, and injuries, which shall be designated as the 'Department of Public Health.'" The following subjects shall be taught in said Department: Hygiene, sanitary chemistry, bacteriology, medical zoology, biochemistry, sanitary administration, sanitary inspection, national and international dangerous occupations, sanitary engineering, comparative medicine, insects as agents in the transmission of infectious disease, international law as affecting sanitary regulations, constitutional and statutory law as affecting sanitary regulations, the history of preventive medicine. Section 4 says: "Courses in the Department of Public Health shall be open to candidates for the degrees of Master of Arts, Master of Science, Civil Engineer, and Doctor of Philosophy, under the conditions set forth." Section 15 reads in part as follows: "This ordinance shall not go into effect until pledges for an endowment have been secured for the full amount of \$200,000, or a subscribed guarantee fund extending over a period of 5 years, which will produce \$10,000 per annum for said period."

WESTERN STATES.

Measles at Madison.—Recent information from Madison, Wis., states that an epidemic of measles prevails among the university students at that place. It is said that more than 100 are now victims of the disease, which was first noticed about 2 weeks ago. Active measures are being taken to suppress the epidemic.

Do They all Chew the Weed in Milwaukee?—According to newspaper reports, Mayor Rose has vetoed the anti-expectoration ordinance passed by the Council, on the ground that it was unreasonable under the present conditions. The ordinance passed after the sidewalk part of it had been omitted,

and its provisions were confined to public buildings and street cars. The Mayor says he is in sympathy with the idea, but holds that it is a necessity to spit in this climate, and that an ordinance should be passed to provide spittoons for all public places before an antisputting ordinance is enforced.

High Mortality Rate from Pneumonia in Chicago.—The Bulletin of Chicago's Health Department for the week ended March 5 says: With 56 days more of the pneumonia season remaining the "upwards of 2,100 deaths from pneumonia," predicted in the Bulletin of October 24, ultimo, are already exceeded. Between November 1, 1903, and March 5, 1904, a total of 2,186 deaths from the disease have been reported. If the last 14-years' daily average of such deaths be maintained until the end of April the death roll of the new "Captain of the Men of Death" will number about 2,800, or a third more than was anticipated. Pulmonary tuberculosis, also, threatens to exceed the estimated 1,300; there have been 970 tuberculosis deaths reported in the 126 days since November 1, and if the daily average be maintained during the next 56 days the total tuberculosis deaths will be about 1,400, or about 8% more than the estimate.

Chicago's Health Department and Antitoxin.—Chicago's Bulletin of the Health Department, for the week ended March 5, says: The Health Department is again prepared to furnish standard diphtheria antitoxin—from the bacteriologic laboratories of the New York Department of Health—to every physician of Chicago in the following manner: 1. Physicians may obtain antitoxin free from the antitoxin stations of the department for the gratis treatment of their charity cases. 2. Physicians may have their prescriptions for antitoxin to use in their paid practice filled by any antitoxin station at the following (present) prices: No. 1 (1,000 units), 75 cents; No. 2 (2,000 units), \$1.25; No. 3 (3,000 units), \$2.25. Free antitoxin is furnished by the stations on the application of any physician, who gives a receipt for the amount of antitoxin supplied, which receipt contains the following certificate: "I hereby certify that the family of this patient is unable to pay for the antitoxin; that the case is urgent; that I am attending without fee, and that I will report the termination of the case on the postal-card form of the Health Department furnished by the druggist." In the body of the receipt is given the name of the patient and the exact residence address. This—in order to refer what is, presumably, a case of destitution to the Bureau of Charities for such further assistance as, upon investigation, may be found necessary. All cases of charity antitoxin will be investigated by the bureau. But this will not be allowed to delay the prompt administration of the remedy. The antitoxin will be furnished first; the investigation will follow.

FOREIGN NEWS AND NOTES

GENERAL.

Dogs Trained to Carry First Aid to the Injured.—The Russian Kennel Club has offered to provide the Red Cross Society with dogs trained to find and relieve the wounded on the battlefield and in rough country districts. The offer probably will be accepted. These dogs carry restoratives and a first aid package attached to their collars.

What Medicine Has Done for Japan.—In these days original Japanese contributions to medical science are taken as a matter of course, yet it's worthy of note that it was a recognition of the superiority of Western medicine that first led the Japanese to study and adopt European life and language and methods. Before the year 1867 the only European language known to the Japanese was Dutch, which was studied by interpreters as a medium for acquaintance with Western medical science. Possibly the choice of Dutch may ultimately be traced to the influence of Boerhaave, the famous physician of Leyden from whom, as it happens, Peter the Great took lessons in 1715.

The Jewish Doctors Forced into Russian Service.—An exchange says: A dispatch from St. Petersburg gives curious particulars of the turn taken by Russian anti-Semitism in war preparations. An enormous percentage of Jews has been sent to the front, including most of the Jewish doctors in St. Petersburg. Out of 180 medical men who left at the beginning of the month, 110 were Jews. This measure was taken for two reasons, although it is against the wish of the Minister of War. One reason was that the Jewish savants are all supposed to be Liberals, whose presence in Russia in critical times is considered undesirable. The other reason was that reprehensible influence was brought to bear on behalf of certain non-Jewish practitioners, who are only too glad to get their Jewish rivals out of the way. The Jewish doctors sent East are deprived of part of their emoluments, and receive only 900 roubles and traveling expenses, whereas Christians get 1,250 roubles. Pressure is being brought to bear upon those Jews whose presence is tolerated outside the ghettos by subordinate officials and police agents, who claim "voluntary contributions" for Red Cross Work, the naval fund, and other institutions.

Röntgen Rays and the Russian Police.—An exchange gives the following: The Russian police make practical use of the röntgen ray. At Kief, recently, a drunken prisoner was robbed of about \$300 by cellmates. They denied the crime, but two-thirds of the money was found in their clothing and the röntgen ray revealed the other hundred dollars, which was in gold snugly stowed away in their respective interiors. They had swallowed it. Against detectives provided with the röntgen ray, the radium ray, and other marvels yet to come, the criminal of the future will need to be armor-plated like a battleship.

Curing Drunkards in Norway.—A novel method is that adopted in Norway for turning a drunkard from the error of his ways. The patient is placed under lock and key, and is fed at frequent intervals on bread saturated with port wine. For the first day this is no doubt palatable fare; on the second it begins to pall, and fails to tempt the appetite; on the third day the prisoner turns from it with obvious distaste. But he must either eat or starve; and before the eighth day sets him free he has acquired such a loathing for intoxicants that he, more often than not, spends the rest of his days as a rabid teetotaler. At least, that is what is asserted.—[*London Westminster Gazette.*]

Patent Health Tent.—Among the new inventions chronicled in *The Lancet*, London, England, January 30, is a patent health tent, manufactured by Messrs. S. Wilson & Co., of Bedford street, Belfast, who have sent to Bartholomew's Hospital an illustrated description of their "patent health tent," in which there are no poles visible when the tent is erected and an air space 6 inches wide is provided between the inner and outer layers of canvas for the purpose of reducing variations of temperature. A center pole is not used. A special feature of the tent is stated to be the employment of stretchers and of cross-stays connecting the vertical poles together in such a manner as to be adjustable lengthwise. These stretchers are, in fact, strong spiral springs, and in this way the canvas is firmly held both in wet weather and in dry. The makers believe that the tent will be found useful in the open-air treatment of tuberculosis and in the isolation of cases of infectious disease.—[*Daily Medical.*]

The Mosquito and Malaria.—An exchange says: Professor Royce, recently returned from Egypt, gave an interesting account of the success which has attended the efforts to extirpate the mosquitos and malaria from Ismailia. He said that when Major Ross visited Ismailia in September, 1902, there were 2,000 cases of malaria annually in a population of 9,000 people, of whom 2,000 were Europeans. The authorities at Ismailia loyally carried out his suggestions as to filling up marsh land close to the town and cleaning out small irrigating channels and stagnant waters. That involved an expense of \$22,000, and at the same time they organized a drains brigade and a petroleum brigade, and now people could sleep in any of the houses in the European quarter without mosquito nets. Malaria cases had been reduced from 2,000 a year to 200. As a matter of fact, there were no fresh cases of malarial infection in Ismailia; there had been no deaths among Europeans during 1903, and only 4 among natives, against 30 deaths the year before. The improvement was so wonderful that Prince D'Arenberg, president of the Suez Canal Company, hopes soon to see Ismailia the sanatorium and watering place for Cairo. Major Ross, who was present, remarked that the success of the antimalarial campaign at Ismailia had taught 2 things—that it was possible to rid a large town entirely of mosquitos, and that it was equally possible to eradicate malaria. He had been asked to draw up a report as to malaria cases in India, which were responsible for 300,000 admissions to hospitals from the troops and jail prisoners. With the Ismailia figures before him, he felt confident that these high figures would be reduced soon by at least one-third.

OBITUARIES.

Jefferson Cushing Gallison, from heart disease, at his home in Franklin, Mass., February 22, aged 62; a graduate of Brown University in 1875, The College of Physicians and Surgeons, Boston, in 1888, Tufts College, Boston, in 1894, and Harvard Medical School, in 1895. He was one time member of the Legislature; demonstrator of anatomy at the College of Physicians and Surgeons; lecturer on surgical pathology in Tufts Medical College, and member of the Massachusetts Medical Society.

Vernanus Morse, at his home in Brooklyn, March 9, aged 85; a graduate of Dartmouth College and of the University of New York. He began practice in New York City, in 1849, and was one of the founders of the Y. M. C. A. in New York, in which organization he was particularly conspicuous. He was treasurer of the New York Medical Union for several years, and was well known and revered in the community in which he lived.

John P. Edge, at his home in Downingtown, Pa., March 7, aged 82; a graduate of Jefferson Medical College, in 1846. For several consecutive years he was a member of the Pennsylvania Legislature. He was the author of the bill establishing the Board of Agriculture, a member of the Chester County Medical Society, and one time member of the Board of Agriculture of the State of Pennsylvania.

Dallis M. Wick, after an illness of several months, at his home in Cedar Falls, Ia., March 1, aged 63; a graduate of the Chicago Medical College in 1874; vice-president of the Iowa State Medical College; member of the Iowa State Association of Railway Surgeons; member of the American Medical Association and a prominent physician of northern Iowa.

William H. Highlands, at his home in Newtown, Ohio, February 29, aged 81; a graduate of the Medical College of Ohio, Cincinnati, in 1850. He was the oldest physician in Hamilton county and he served as surgeon in the Civil war and was at one time a member of the Ohio Legislature.

Robert S. Henry, from Bright's disease, at his home in Charles town, W. Va., March 10, aged 52; a graduate of the U. S. Naval Academy, Annapolis, and from the University of Maryland. He had practised in Charlestown since 1882, and was prominent in medical circles.

Guy B. Chase, from pneumonia, at his home in Cleveland Ohio, February 26, aged 52; a graduate of the University of Wooster, Cleveland, in 1873; member of the American Medical Association, and professor of dermatology at the Cleveland College of Physicians and Surgeons.

Thomas S. Galbraith, at his home in Seymour, Ind., February 23; a graduate of the Medical College of Ohio, Cincinnati, in 1866; one time superintendent of the Central Indiana Hospital for the Insane, Indianapolis, and of the Oklahoma Insane Hospital at Norman.

David L. Wallace, from pneumonia, at his home in Newark, N. J., February 29, aged 48; a graduate of the Bellevue Hospital Medical College, New York, in 1875; secretary of the Newark Board of Health, and member of the American Medical Association.

Arthur Collis Gibson, from septicemia, at his home in Bangor, Me., February 21, aged 43; a graduate of the Medical School of Maine, at Bowdoin College, in 1885; a member of the Maine Medical Association, and a prominent physician of Bangor.

Robert J. Wilding, from heart disease, at his home in Malone, N. Y., February 24, aged 67; a graduate of Apothecaries' Hall, London, England, in 1856. He was secretary of the Franklin County Medical Society at the time of his death.

James Billingslea, at his home in Baltimore, March 2, aged 47; a graduate of the University of Maryland. He had resided in Baltimore 16 years, and was at one time State Medical Examiner for the Royal Arcanum.

Ida R. Gridley Case, a specialist in eye and ear diseases, at her home in Collinsville, Conn., March 9. She received her medical education in Boston, and was considered one of the best experts in the State.

Eldridge G. Hard, from malignant disease, at his home in Medina, Ohio, February 23, aged 77; a graduate of the Cleveland Medical College in 1850. He was surgeon in the U. S. Army during the Civil war.

Charles T. Whybrew, of Bright's disease, at his home in New York, March 8, aged 62; a graduate of the College of Physicians and Surgeons, and a member of the New York Medical Society.

Frank E. Baker, at his home in Newark, March 1, aged 48; a graduate of the College of Physicians and Surgeons, New York City, and ex-superintendent of the Newark City Hospital.

Thomas B. Cosford, from tuberculosis, at his home in Redlands, Cal., February 26, aged 57; a graduate of Trinity Medical College, Toronto, in 1876. His home was at Lockport, N. Y.

Peter Arnold, at his home in Wellsville, Mo., February 25, aged 35; a graduate of the Washington University, St. Louis, in 1895. A member of the American Medical Association.

W. S. Ruby, committed suicide by shooting, at his home in Riverside, California, February 22; a graduate of the Homeopathic Medical College of Missouri, St. Louis, in 1878.

Theophilus Smith, at his home in Wausau, Wis., February 27, aged 87; a graduate of Jefferson Medical College, and one time post-master of his native city.

Frank M. Severson, from pneumonia, at his home in Seneca Falls, N. Y., March 1, aged 40; a graduate of the College of Physicians and Surgeons, N. Y., in 1889.

Hermann Motter, at his home in Reading, Pa., February 22, aged 83; a graduate of the University of Giessen, Germany, in 1846. He retired from practice in 1891.

William C. Mills, from heart disease, at his home in Chateaugay, N. Y., February 23, aged 38; a graduate of McGill University, Montreal, in 1893.

William D. McClees, at his home in Wichita, Kansas, February 25, aged 42; a graduate of the University of Pennsylvania, in 1885.

Middleton Stuart Hanckel, at his home in New York, March 12, aged 76; a graduate of the Charleston Medical College, S. C.

Anna E. Mills, from tuberculosis of the intestines, after a long illness, at her home in Denver, February 21.

Enoch Lewis, from pneumonia, at his home in Oskaloosa, Ia., March 2, aged 67.

Edward Downes, at his home in Kensington, Philadelphia, March 11, aged 65.

CLINICAL NOTES AND CORRESPONDENCE

[Communications are invited for this Department. The Editor is not responsible for the views advanced by any contributor.]

THE PROBLEM OF POTASSIUM IODID.

BY

ALFRED GORDON, M.D.,
of Philadelphia.

To the Editor of American Medicine:—The inquiry concerning the internal administration of potassium iodid is undoubtedly a question of interest and of great practical importance, and Dr. Payne's correspondence in *American Medicine*, February 27, should be commented upon by all who have had a more or less large experience with that drug.

The iodids are of great utility not only in hemiplegia, but also in many other conditions indicating an organic involvement of the cerebrospinal axis. As far as results are concerned, if on one hand some cases are not at all benefited by the drug, there are on the other hand diseases which are very favorably influenced by it. Among the latter syphilis of the nervous system is the most fortunate of the organic diseases. The consensus of opinion as it stands now is that syphilitic infection (hereditary or acquired) is the principal cause of many forms of cerebrospinal affections (tabes, for example). It should, however, be distinctly understood that there is a capital and fundamental difference between a genuine syphilitic affection of the nervous system and those systemic diseases in which syphilis played perhaps a certain role as a causative factor. In the latter case the pathologic condition is expressed in well-established tract degenerations which run a chronic and a well-defined course, upon which the old syphilitic poison has no more effect. These are the so-called parasymphilitic affections of Fournier. When we speak of cerebrospinal syphilis we have in view a pathologic condition, which is due to a direct and immediate effect of the syphilitic poison upon the nervous tissue, and according to the portion involved, we have a great variation of symptoms. It is true, they may be transitory in character, may disappear and reappear, may at one time affect a certain portion of the brain and at another the spinal cord *in toto*, or only in part, or both at the same time. One may improve, the other persist, or both disappear and reappear. This multiplicity and variation of manifestations, the repetition of symptoms, are due to various localizations of syphilitic formations and infiltrations (gummas). This is the characteristic feature of cerebrospinal syphilis, and in this disease more than in any other form of organic nervous diseases the iodids are useful. This affection is more common than it is generally supposed, and indeed, it is frequent. The questions raised by Dr. Payne are therefore very important. Is there a method for the administration of the drug? as the doctor puts it. If it can be called method, it will consist merely of the general principle applied in therapeutics. Test the idiosyncrasy of the patient, and for this begin with small doses; .32 gm. (5 gr.) 3 times daily for an adult is the proper dose to begin with (at least in my experience), although I have known patients who showed iodism with .26 gm. (4 gr.) doses. It is not difficult to manage if this principle is borne in mind. The dose should be increased every other day, .53 gm. (8 gr.) 3 times daily, and then .65 gm. (10 gr.) 3 times daily, etc. When the dose of 1.3 gm. (20 gr.) is reached, the increase may be made somewhat more rapidly; give 1.6 gm. (25 gr.) 3 times daily, and increase only 4 to 5 days. Of course, the patient must be seen often, and at the slightest symptoms of intolerance discontinue the drug for 1 to 2 days, and then again follow the same plan. In this manner I have very rarely observed undesirable symptoms and succeeded in having my patients accustomed to daily absorption of very large quantities of iodids. As to the question of a maximum dose, I was never much concerned about it, as it was not necessary. In fact, there is no possibility of establishing, or even giving approximately, a maximum dose; for one patient the maximum dose may be .32 gm. or .65 gm. (5 gr. or 10 gr.), for another 20.1 gm. (310 gr.) 3 times daily (a case of tumor in an adult), and still for another 21.1 gm. (325 gr.) 3 times daily (a case of cerebrospinal syphilis). A boy of 12, being treated for a cerebellar tumor, is now taking 7.3 gm. (112 gr.) 3 times daily without the slightest symptom of iodism. In this particular case there was an intoler-

erance at the beginning, because of gastric disturbances of several years' standing. As soon as the condition of the stomach improved the intolerance of iodids disappeared. This latter circumstance, namely, the state of digestion, is a very important factor in establishing the tolerance or intolerance of iodids. We therefore see that with a proper management and reasonable discrimination we can in the large majority of cases avoid iodism or other undesirable symptoms in administering iodids.

In closing, I wish to call attention to this fact, that in the majority of my cases I prescribed sodium iodid instead of potassium iodid. Perhaps this is also one of the reasons of the great tolerance of the drug, and since the results are identical with those of potassium iodid (at least in my experience), it is perhaps desirable to apply it more extensively than therapeutists usually do.

THE DIAGNOSIS AND TREATMENT OF DIPHTHERIA.¹

BY

T. CLARKE MILLER, M.D.,
of Massillon, Ohio.

Probably almost all workers in bacteriologic laboratories believe that it is fully settled that a diagnosis of diphtheria arrived at clinically at the bedside is valueless. While the producers of antitoxin and many physicians agree that only one therapeutic measure is worthy of mention, some go so far as to condemn the neglect to use antitoxin in any given case of diphtheria, or even in any suspicious case.

It is an unfortunate event in the pursuit of truth when a difference of opinion has to be expressed apologetically. If the evidence at hand satisfies one and compels the conviction that the last word has been said as to diphtheria and its treatment, I concede that one has a right to such opinion. However, though the subject has been cleverly opened up, it is by no means exhausted.

The discovery of the Klebs-Loeffler bacillus and the evidence presented of its causative association with diphtheria, are matters of immense importance to physicians and to humanity.

The presence of the germ in the absence of the more palpable evidence of the disease, or in the doubtful case, has a significance which can hardly be said to be fully interpreted. The initiative still rests with the trained senses and the experience which enables us to recognize the disease, as we recognize most other diseases—by characteristics which are obvious to the organs of sense, unaided except by the reasoning faculties. The presence of the Klebs-Loeffler bacillus is not sufficient evidence that diphtheria is present, and its presence is not conclusive evidence that the disease is diphtheria. It does not seem to exclude other infections, and is present when there is no infection.

The term diphtheria has a more specific application than formerly. At one time inflammation of the throat attended by a membranous exudation might properly be named diphtheria. At present diphtheria is an exudative inflammation attended by a specific germ—the Klebs-Loeffler bacillus. The exudative inflammations of the throat are not all diphtheric in character, and those that are not are assumed to be less threatening to life and less important from a sanitary point of view than the true diphtheric disease, characterized by the membranous exudate and *Bacillus diphtheriae*.

The concession of less gravity to these infections ought not to give rise to the assumption that any exudative inflammation invading the throat or upper air passages, is devoid of danger, for it is a matter of record that exudative inflammations due to other than the Klebs-Loeffler germ, have not infrequently proved fatal. All exudative inflammations are probably infectious and should be managed as such by the physician and sanitarian. A genuine diphtheric exudate which can be brought well into view can be pretty easily and confidently recognized and differentiated. I have not neglected to test repeatedly the foundations of this confidence by a bacteriologic inquiry, the result of which has not failed to fortify my diagnosis. I have taken this course to satisfy myself and those who contributed their manipulative skill.

The exudate due to *Bacillus diphtheriae* is more substantial and continuous than that resulting from other infections. It is more regular in its ovoid outline, more often spreads from a single center, and has an angry red boundary, which of itself is, I believe, characteristic. I make this statement, first, because I believe it, and second, because, in the interests of truth, I am willing that it should be questioned or disproved. There are, no doubt, obvious features in a diphtheric exudate which point unerringly to the nature and characteristics of the causative germ.

There are cases of diphtheric infection without an exudate which can only be presumptively diagnosed, clinically, from the known fact of exposure. An exudate will appear later, in the absence of treatment, but until it does appear the positive diagnosis must depend upon the bacteriologic test. Children who have been exposed to diphtheria may become sick, with high fever, headache, nausea and a sore throat several hours before an exudate appears. The microscope will show the presence of the germ, but aside from that fact, whatever your method of treatment may be, the case must be at once handled as diphtheria.

Fortunately, a diagnosis need not often depend upon bacteriologic findings, for in no other disease is prompt action in the right direction more urgently demanded. In diphtheria every hour of delay is likely to be an hour's progress toward a fatal end. Again, many physicians have not the appliances nor the manipulative skill necessary to a bacteriologic determination of such questions, and are practically out of reach of any one who is equipped for such work. To a large percentage of the profession a bacteriologic diagnosis is out of the question. Observation and study will qualify the physician to make a diagnosis, clinically, and a clinical diagnosis is almost always sufficient—while a microscopic diagnosis, alone, is never sufficient.

While recognizing the virtues of antitoxin, it is well not to abandon, or at any rate not to forget other therapeutic measures founded on the experiences and observations of the past. It is quite possible that we may be several hours away from a fresh and reliable supply of antitoxin and even when it has been procured, it is more likely to be from the old than from the newer stock.

It is to be hoped that the time may come when antitoxin can be so prepared as to retain its virtues indefinitely, but until that time, if other drugs can show good results, we will not do well to ignore them.

Diphtheria, taken in hand at the outset, quickly yields to antitoxin, and also quickly yields to other means. In this paper it might not be inappropriate to consider the various therapeutic lines which might be followed with fair promise of success, but this would be wearisome and not perhaps altogether inoffensive. So I will only refer to the method of treatment which I am in the habit of following.

For more than 20 years my main dependence in the treatment of diphtheria has been mercurous chlorid. In the early stages the disease is checked in a few hours and under complete control in a few more hours. The early fever and sickness are almost immediately relieved, and very soon the progress of the local disease is stayed and a feeling of comparative wellbeing takes possession of the patient. These are the most definite features of a typical antitoxin action. The action of quinin on malarial fever is not more quickly nor more decidedly marked, and is apparently not more nearly specific. Of course, when the disease has gone on to a secondary systemic infection, generally mixed in character, the results are not so prompt under this or any other treatment. The administration of mercurous chlorid fortifies the system against the toxins of diphtheria, and at the same time, inhibits the growth of the diphtheria bacillus. There is also considerable evidence that mercurous chlorid has an inhibitory effect upon the growth of other exudation producing germs. (The apparent relationship of these other exudates to true diphtheria justifies me in noting this fact.) The Klebs-Loeffler germ is killed or crippled in situ, thus greatly simplifying the task of protecting others from infection, for the germs of diphtheria, which have made their escape from the host in a vigorous condition may be very difficult to reach and destroy, and are liable to

¹ Read at the Toledo meeting of the Ohio State Pediatric Society May, 1902.

assert themselves at unexpected times and in unexpected places. I am not sure that it is claimed, but I am willing to concede, that antitoxin may also, to some extent, inhibit or destroy the developmental vitality of the Klebs-Loeffler germ and render it less potent for mischief when transferred to a new host. If so, it is susceptible of proof. If it has been proved I have overlooked the proof. (Councilman, Mallory and Pearce, in their wonderfully interesting report on 220 fatal cases of diphtheria, almost all of the patients being treated with antitoxin, do not mention any difficulty in developing cultures.) In 20 years I have not seen a case of post-diphtheric paralysis among the patients I have treated. I believe it is not claimed that the liability to paralysis is at all diminished by the use of antitoxin. Some claim that the liability to this sequel is increased. I incline to think it is not. I have failed to find any trouble with the kidneys attending or following diphtheria when treated with mercurous chlorid. I have not had a single case of extension to the larynx after treatment had been begun.

In cases seen in the preexudative stage the disease may be throttled before an exudate appears, and if the exudate has just appeared, to an extent sufficient for recognition, the mercurous chlorid generally triumphs within 24 hours. I have almost given mercurous chlorid a certificate of excellence as an immunizing agent and I do not hesitate to add that I doubt whether there is anything better at present within the reach of the therapist.

I think I appreciate the hazard of my position. I am aware that in the present state of the public, as well as of the professional mind, we can afford to lose a patient if we give antitoxin promptly and freely, while if we lose a patient under any other treatment many physicians seem ready to dictate to the laity a verdict against us of manslaughter or worse.

In laryngeal diphtheria I would use antitoxin without delay and freely. In this really formidable type of the disease nothing else has such a record to its credit. Early in cases in which the nose is invaded, antitoxin is advisable; later, when secondary systemic infection is present I could not in the light of my experience bring myself to trust antitoxin to the exclusion of other measures.

It is, however, fairly certain that antitoxin, in some way, antagonizes the toxins or supplements the natural powers of resistance more quickly than any other known remedy. This rapidity of action is no doubt partly, if not wholly, due to the method of its administration.

The most formidable cases of diphtheria, aside from the laryngeal form, are mixed infections. The neglected case, I think, is likely in a few days to take on this type. It then becomes a rather poor case for the exploitation of any method of treatment. When a secondary toxic condition has been established I doubt whether antitoxin promises much, and I believe mercurous chlorid will give better results and I would prefer to trust it if compelled to a choice, though I am not aware of serious objections to its use in connection with antitoxin. I have seen no troublesome cathartic effects from the use of mercurous chlorid, no prostration, no threatened salivation and no undesirable effects in any way. (In looking over my record I find that of the last 80 patients I treated I lost but one.) Of course, one man's experience is not a basis for conclusions, yet it is of some importance to himself. I do not claim to have discovered anything, I may, however, have pushed this particular line of inquiry a little further than some others have, and possibly a little more systematically.

There are a few reasons why one might prefer to use other means rather than antitoxin: 1. Antitoxin is very expensive, and I am not sure that we can expect much reduction. 2. Confidential relations between the physician and his patient are sometimes seriously imperiled when it becomes his duty forcibly to administer hypodermically a large dose to a child 2 to 4 years old. Subsequent necessary inspection of the throat will often not be submitted to without vigorous muscular protest. A struggle is to be deplored, and might be dangerous. The administration of antitoxin is brutal when it is unnecessary. 3. Not infrequently the expense falls on the physician himself. I do not advance these objections as having sufficient weight to dissuade one from doing what is necessary. Such

considerations weigh nothing against a measure which is necessary to save human life. Bacteriology ought to furnish some evidence as to the effects of treatment which would be no less valuable than that it offers in diagnosis. As I am situated, a case of diphtheria is not always at hand for diagnosis, or treatment, but in the past 6 years I have had some opportunities to study the effects of treatment aside from its more palpable results.

Dr. D. W. Gans has contributed his knowledge and manipulative skill in the way of bacteriologic work with a patience and enthusiasm which is inadequately rewarded by appreciation. I will briefly summarize the result of these studies, because I believe this to be an important feature in the discussion of this subject:

1. In every case clinically diagnosed as diphtheria, the Klebs-Loeffler bacillus has been found.

2. A swab taken from the throat *before treatment*, never failed to show the bacillus under immediate coverslip examination, and it never failed to grow beautifully in from 15 to 24 hours.

3. After 12 to 24 hours' treatment the bacilli were present on the coverslip, but showed no growth in a culture medium after 24 hours, and only an extremely feeble growth after 48 hours' incubation. It remains to be determined whether by repeated cultures the germ recovers its virility or becomes completely sterile. In a number of cases the second crop was very feeble or a complete failure, and cultures could not be continued.

4. After the exudate had disappeared, though bacilli were sometimes present, cultures always failed.

5. In patients thoroughly exposed to infection, and developing the initial malaise, fever, headache, and sore throat, but showing, as yet no exudation, the bacilli were present and grew luxuriantly. After 24 hours' treatment with mercurous chlorid the bacilli were still present, but failed to grow, and no exudate appeared.

It would seem that if the growth of the bacilli in a culture medium is inhibited, the danger of these bacilli as agents of infection must be at least to a corresponding degree mitigated.

If this be true, it is entitled to serious consideration from a sanitary and hygienic point of view.

I append an outline of the management of diphtheria:

Isolate the patient as completely as possible from those susceptible. Strip the sickroom of woven fabrics, books, papers, and bedding, beyond what is absolutely necessary for the comfort of the patient. An open fireplace with at least a little fire, is very desirable, in order to maintain a movement of air toward the sickroom, and for the destruction of soiled cloths, etc. Only such books, papers, and playthings should be about the patient as may be burned at the conclusion of the sickness. Keep formaldehyd gas in the room to the verge of discomfort. Secure plenty of fresh air, provide mercuric chlorid solution in basins to receive all secretions coming from the mouth or nose. An abundant supply of worn cotton goods or cheese-cloth in moderate sized pieces should be used to receive secretions, and destroyed at once by fire.

If there is no fire in the room, wrap these soiled cloths in paper and take them to the fire, or place them immediately in mercuric chlorid solution. Use as few dishes as possible, and keep them separate from those used by the well. Bathe the patient every day, and for several days after recovery destroy or thoroughly disinfect the cloths used in bathing. Encourage the use of plenty of water for washing the mouth and throat, and drinking plenty of water materially aids the elimination of poisons from the blood.

Burn freely, boil freely, disinfect freely with mercuric chlorid and formaldehyd. These, up to this point, are sanitary measures.

The medication is very simple. I give 6 mg. ($\frac{1}{10}$ gr.) of calomel every hour for 12 hours to 24 hours, then continue the same dose once in 2 hours. I generally provide a gargle of potassium chlorate with tincture of iron or formaldehyd to be used about once in 3 hours. I direct the patient to take plenty of milk and other liquid foods, and anything else he will eat.

Other members of the family should be watched, and if any should be feverish, nauseated, or have aching of the bones or pain in the head, I would put them on 6 mg. ($\frac{1}{10}$ gr.) doses of calomel at once. I begin the calomel at once if any child who has been exposed shows a real indisposition. If I find that the exudate has originated in, or extended to, the larynx, I use antitoxin at once. If the nose is involved seriously, it is well to use antitoxin, though not to the exclusion of the calomel. I would omit the antitoxin rather than the calomel. I insist on quiet, especially in severe cases, and give alcoholic stimulants or strychnin as needed, but not as a routine treatment; generally neither is needed.

ORIGINAL ARTICLES

THE PATHOLOGY AND SURGICAL TREATMENT OF PANCREATIC DISEASES.*

BY

JOHN B. DEAVER, M.D.

Surgeon-in-Chief, German Hospital, Philadelphia.

AND

GEORGE P. MÜLLER, M.D.,

Instructor in Surgery, University of Pennsylvania; Assistant Pathologist to the German Hospital, Philadelphia.

The experimental researches which have been made of recent years into the etiology and nature of pancreatic disease have established the pathology. The production of hemorrhagic, suppurative, and gangrenous pancreatitis in animals by the injection of acids, alkalies, bile, bacteria, etc.; the histology of the development of the islands of Langerhans; the importance of the latter in the pathology of diabetes, and, finally, the creation of chronic pancreatitis by ligature of the ducts, are the most important achievements of the experimental pathologists¹ of today.

A few words as to the special anatomy of the gland, having a direct bearing upon the pathology, are important enough to bear repetition:

1. The pancreas has not a distinct capsule, being surrounded by areolar tissue only.
2. The accessory duct of the pancreas has no outlet into the duodenum, Opie² states, in a third of all individuals.
3. The secreting acini of the pancreas terminate in ducts which finally empty into the duct of Wirsung, the latter, together with the common duct, forming a conical cavity, the ampulla of Vater, which empties into the duodenum by a minute opening.
4. The common bile duct in its lowest 2 cm. to 7 cm., is embraced more or less completely by the head of the pancreas.
5. Certain columns of cells within the lobules of acini, the islands of Langerhans, have no communication with the ducts, are not infected through them, are not involved by chronic obstruction of the main duct and only become diseased late in the process of chronic interlobular inflammation, or primarily in the interacinous pancreatitis.

As the extent of this paper hardly admits of any extended discussion of the pathology, the description of the more common lesions only will be referred to.

Acute pancreatitis with its fearful rapidity of progress and great mortality is essentially a peritonitis of the upper abdomen, with varying lesions in the gland itself, and often the diffused fat necrosis which may extend to the fat in the epiploic appendages of the sigmoid, or to the mesoappendix on the right. Whether the causal factor is an ascending infection from the duodenum or retrojected bile from the obstruction of a stone in the ampulla of Vater, destruction of the parenchyma of the pancreas ensues, and one of 2 types of disease presents itself.

Acute hemorrhagic pancreatitis is an affection peculiar to the pancreas and undoubtedly due to the complexity of the ferments and of the internal secretion. If a calculus in the presence of infection obstructs the common bile duct alone, the retained infectious bile produces lesions of the ducts, gallbladder, and liver, suppurative in type, but never of the hemorrhagic and often gangrenous character observed in the pancreas. But should the ampulla of Vater be plugged by a gallstone, in the absence of an accessory duct, the retained secretions of the pancreas, retrojected bile, and various infectious agents may produce the wellknown hemor-

rhagic disease. This impaction of a gallstone more nearly explains the sudden onset than any other. The experimental production of hemorrhagic pancreatitis, typical and convincing as it may be, does not explain entirely the pathogenesis in the human subject. If cases of hemorrhagic pancreatitis are more closely studied it is probable that those of sudden onset and rapid, often fatal, progress will be found in the great majority of instances to be due to this obstructing action by a gallstone, either in the ampulla or its immediate vicinity; while those more gradual in onset, and often becoming subacute, will be more directly traceable to an infectious inflammation about the ampulla. It should be recalled in this connection that the formation of calculi in the gallbladder or biliary ducts is directly dependent upon a primary infection, and that at the time of the impaction in the ampulla the bile is probably always more or less infectious.

The onset of acute hemorrhagic pancreatitis is rapidly followed by destruction of part or the whole of the parenchyma of the gland. The pancreatic secretion, acting upon cells injured by retained ferments, infection, etc., causes areas of necrosis and hemorrhage. The

Fig. 1.—Acute pancreatitis (Case 12). Intense bleeding in the interlobular connective tissue.

bleeding is at first confined to the interlobular connective tissues and gradually increases until large areas or even the entire gland is implicated. The necrosis of the cells is marked at first by a solution of the nuclei, but later the entire outline of the acini becomes lost. An inflammatory reaction, marked by the presence of a large number of polynuclear leukocytes, is present from the beginning. In advanced cases the pancreas appears large, dark, and tightly distended with blood of a blotchy red or purple color and surrounded by a necrotic mass of blood and fat, often of a chocolate color. In microscopic sections of such a pancreas the interacinous, interlobular, and peripancreatic tissue is seen infiltrated with blood (see Fig. 1), the intact bloodvessels distended with blood, and their walls are swollen and cloudy. The acini, if identified, are barely discernible, though their nuclei are lost, and the cells are granular and cloudy in appearance. In various areas the destruction of the gland becomes total and nothing can be discerned except a structureless granular debris.

In other areas of the gland a line of demarcation is sharply drawn between necrotic and fairly living tissue.

* Read before the Medical Association of Greater New York City, February 8, 1904.

In the zone between the two, nuclear fragments, red blood cells, and leukocytes are observed, with hyaline capillary thrombosis. (See Fig. 2.) In those cases which have lasted for some time, active proliferation of new connective tissue and fat drops replace the destroyed parenchyma.

Gangrenous pancreatitis is the termination of the acute lesion, and naturally follows the widespread death of tissue observed in marked cases of hemorrhagic forms.

The organ is large, friable, slate, brown, or purple in color, and upon section presents a mottled red and black appearance, without visible evidence of any structure, except the duct of Wirsung, which may be observed near the center of the gland. The pancreas is surrounded by a foul-smelling chocolate-like material.

Suppurative pancreatitis, or abscess of the pancreas, is due to infection by bacteria, either ascending from the duodenum or through the circulation. The pus is observed as multiple small abscesses or metastatic deposits, distinguishing this form from the hemorrhagic disease, with infiltration and diffusion of the leukocytes into the already formed necrotic tissue. Hemorrhages may be coincident, and usually occur in the interstitial

Fig. 2.—Acute hemorrhagic pancreatitis, necrosis (above). Zone of leukocytes and red cells, acini, swollen and cloudy (below).

connective tissue. The abscess, if large, may open into the peritoneal cavity, more rarely externally, and if primary in the pancreas, may infect the portal vein and liver.

Fat necrosis has been referred to, and is an interesting chemic reaction whereby the pancreatic ferment, by virtue of its fat-splitting element, infiltrates the fat in the peritoneal cavity, induces specks of necrosis followed by the production of the crystalline calcium salts, and may either break down or subsequently disappear. These areas appear as scattered white points, varying in size from 1 mm. upward, and surrounded by a thin wall of leukocytes. The latest investigations, those of Wells,³ place the dissemination as occurring through the lymphatic system. At the present time their appearance in the mesentery and omentum, when the abdomen is opened at operation, must be considered as indicating a grave lesion in the pancreas and a probable fatal termination.

The peritoneum is variously affected by acute pancreatitis. Many cases have been reported with marked dis-

ease of the gland, extensive fat necrosis, and widespread extravasation of blood, and yet the evidence of a true inflammatory reaction was wanting. The peritoneal cavity has been observed as studded with points of fat necrosis, with a transparent peritoneum, and no adhesions whatever. Such instances strongly indicate the chemic nature of the agent causing many of the cases of hemorrhagic pancreatitis. In others, a true and often diffuse peritonitis is present, and especially when the pus in the suppurative form has broken into the peritoneal cavity.

CASE XII.—S. W., aged 39, a male Russian and a tailor by occupation, was admitted to the German Hospital October 14, 1903. The family history is unimportant. He had enteric fever twice, never with jaundice. Suffered frequently from attacks of indigestion and eructations of gas.

Eleven days before admission was seized with sharp shooting pain over the region of the gallbladder radiating downward and to the middle of the back. He vomited some bitter green material during the attack and again several times later. Bowels were constipated, absolutely so, for the first 4 days and the stools are dark brown in color. No jaundice. Suppression of urine at times.

Upon admission he was very ill, temperature was 101°, pulse 108, no jaundice nor cyanosis. The abdomen was distended and tympanitic with marked tenderness over the gallbladder and toward the median line.

Urine revealed a trace of albumin, no casts, no sugar, no bile.

Blood counts October 14, 1903: Hemoglobin, 96%; erythrocytes, 5,616,000; leukocytes, 7,200.

Differential count: Polynuclear, 75%; small lymphocytes, 16%; large mononuclear, 5%; eosinophiles, 2%; transitional, 1%; mast cells, 1%.

October 16, 1903, leukocytes, 8,850.

October 17, 1903, leukocytes, 7,600.

A fluoroscopic examination revealed a shadow in the epigastrium, dense upon the right side with very little movement upon deep inspiration.

Operation.—October 17, 1903. Upon opening the abdomen over the gallbladder, a large fatty omentum was encountered slightly adherent to the parietal wall and speckled with fat necrosis. The pancreas was felt to be somewhat enlarged, hard and rather nodular. There was no fluid in the lesser sac and the foramen of Winslow was open. For this reason a simple cholecystostomy was performed. The bile in the gallbladder was thick and dark, free from calculi, and later revealed the colon bacillus in pure culture. October 23, the patient, who had hitherto been doing very well, ate a quantity of grapes brought by a visitor, vomited, collapsed, and death followed.

No autopsy was permitted, but the operative incision allowed the removal of the pancreas. The fat within the abdomen was speckled throughout with fat necrosis, the gallbladder was surrounded by adhesions, and beneath it some necrotic fat had formed a small, well walled-off collection resembling pus and revealing the colon bacillus. There was no other peritonitis. The liver appeared normal; there was no fat necrosis upon the epicardial fat; the kidneys appeared congested, but were not opened.

The pancreas was surrounded by areas of fat in a state of necrosis, was swollen and in areas mottled, purplish in color, especially near the middle. Upon section the surface was granular and the hemorrhage was observed as confined to the areolar tissue enclosing the organ and extending in fine lines inward, evidently along the interlobular connective tissue.

Areas of necrosis were seen beneath the capsule and in several small areas within the gland near the head. The duct was thickened, congested and patulous. The common bile duct was patulous, the ampulla clear, and the duodenum much congested.

Microscopic sections of the pancreas revealed the usual lesions of acute pancreatitis. The acini are swollen and cloudy, though in some areas they stain sharply. The interlobular connective tissue septums are thickened and infiltrated with blood (Fig. 1) and leukocytes.

The zones of necrotic tissue (Fig. 2) are surrounded by leukocytes and by greatly altered glandular structure. A few thrombi are present in the smaller veins.

Chronic pancreatitis is of immense importance at the present time by reason of the brilliant prospects which surgery offers in the cure of a disease long believed to be incurable and frequently confused, in diagnosis, with malignant disease.

The experimental researches made during the past few years into the pathology of this affection have been spoken of by those who have preceded, and but little remains to be said.

The pancreas parallels the liver in a fairly close manner, when attacked by chronic indurative inflam-

mation, though the lesions observed have a more direct bearing upon the clinical findings. Both organs may become involved through the same etiologic factors of which infection and gallstones bear the chief part. Biliary cirrhosis following calculous cholangitis is becoming better understood and chronic indurative pancreatitis, at least the interlobular variety, has already passed the threshold of correct interpretation.

When obstruction of the duct occurs, the secretion is gradually dammed back upon the gland, infection is favored and the pancreas becomes damaged. The gland, especially at the head, enlarges, and to the palpating hand is hard, frequently nodular. The secretion surface is granular and compact with the replacement of the loose interlobular tissue of the normal gland by that of a dense and scar-like hardness. In more advanced cases, areas of fat are observed to have encroached upon the parenchyma, and finally nothing may remain of the pancreas but a mass of fat held together by strands of fibrous tissue.

Microscopically, the acini are barely altered in the earlier stages with atrophied nuclei and dilated lumina. The interlobular connective tissue is thickened and greatly infiltrated with polynuclear, lymphoid and plasma cells and eosinophiles. The bloodvessel walls are thickened. The islands of Langerhans are unaltered.

As the process of sclerosis advances the glandular stroma becomes replaced by connective tissue and infiltrating fat. Often islets of acini are observed entirely surrounded by fat or connective tissue, which do not contain a trace of glandular cells. The islands of Langerhans may be entirely normal, or compressed and distorted by the contracting scar tissue. At this point, viz., in advanced interlobular pancreatitis, the question as to when the islands become sufficiently diseased to influence the occurrence of glycosuria, is difficult to answer. We have in mind 2 cases, in 1 pronounced glycosuria was present and the islands were normal, except for great distortion by sclerotic tissue. (Figs. 3 and 4.) There was no hyaline degeneration.

CASE XIII.—Male, aged 55. Seen in private practice with Dr. George McCracken. No history obtained, except that he had been a free user of alcohol. In the summer of 1903 he was seized with severe pain in the epigastrium, radiating concentrically. Bowels fairly regular. No vomiting. Considerable distress after eating. His urine revealed considerable sugar and a trace of albumin. This condition continued until January, 1904, when during a very severe attack of epigastric pain radiating upward to the cardiac region, he suddenly collapsed and died. At several physical examinations nothing could be determined except tenderness and slight rigidity in the epigastric region. Dr. McCracken and Dr. Deaver both told the patient that they believed his trouble due to inflammation of the pancreas.

At necropsy only the abdomen was opened; an enormously fatty omentum and mesentery were found with a normal-sized pancreas embedded in fat; no fat necrosis. The splenic artery was hard with flecks of fibrosis, and upon section the pancreas was found to have been invaded by fatty tissue, seemingly replacing considerable of the parenchyma. The duct was patulous. There were no gallstones, and the common duct was patulous.

Microscopic section revealed advanced interlobular pancreatitis with a new formation of connective tissue, thickening of the interlobular tissue, fatty infiltration in places cutting small areas of acini into islets, and thickening of the bloodvessels.

In some of the sections a round-celled infiltration was observed in the interlobular tissue. The islands of Langerhans were often unaltered, often distorted and compressed by fibrous tissue, never the seat of hyaline degeneration. (Figs. 3 and 4.)

In the other case, and one representative of the advanced type of the disease, there was no trace whatever of glandular acini, nothing but fat and fibrous tissue in which the islands of Langerhans stood out prominently and involved, as in the other case, by mere distortion and compression. (Fig. 5.) There was no sugar. In both of these cases there was marked arteriosclerosis, especially of the splenic artery. In the second case pancreatic calculi completely obstructed the duct of Wir-

sung and the gland, as has been said, was in a state of complete atrophy. The condition was found at postmortem examination, after death had occurred from pulmonary tuberculosis.

The history of the case, for which we are indebted to Dr. J. C. Wilson, is as follows:

CASE XIV.—August S., aged 60, a store-keeper, was admitted to the German Hospital March 18, 1903. He was brought from a distance to the hospital, and was in a dying condition when admitted. Neither he nor the relatives with him could give any history of his past or present illness. Physical examination revealed the presence of pulmonary tuberculosis. He complained of some pain in the epigastrium and to palpation a sense of resistance was determined. The urine showed a trace of albumin, specific gravity 1.019, a few hyaline casts, and no sugar. No other examinations were made, and he died on March 21, 3 days after admission.

The necropsy was made by one of us with the following findings:

Tuberculosis of both lungs, double pleurisy with effusion, ascites, parenchymatous nephritis, pancreatic lithiasis, chronic and atrophic pancreatitis, arteriosclerosis of the abdominal aorta and most of its branches, especially of the splenic artery.

The lungs were markedly diseased with cavity formation. The gallbladder was normal in size, pale in color with very thin walls and an atrophic condition of the mucous membrane,

Fig. 3.—Chronic pancreatitis (Case 13). Overgrowth of connective tissue and fat infiltration.

as though this organ had been, at some previous time, greatly distended. All of the biliary ducts were patulous.

Upon opening the transverse mesocolon the pancreas was observed to be extremely soft and fatty, although the configuration of the gland was fairly well preserved (lipomatosis). It was removed, together with a portion of the duodenum, and upon section was found to be a mass of fat, traversed by fine bands of fibrous tissue, bloodvessels, and nerves. The ampulla of Vater was 8 cm. from the pylorus, and normal, as was the opening of the bile duct. The duct of Wirsung was found completely obstructed, greatly dilated, packed with white calculi and with thickened walls. The ducts leading into the main duct contained fine concretions for some distance into the pancreas. The opening of the duct of Santorini into the duodenum was found 6 inches from the pylorus, but could only be probed upward a short distance.

Pancreatic calculi have rarely been diagnosed during life and only once has such diagnosis been followed by operation. They are composed in great part of calcium carbonate, indicating that they are not formed by the precipitation of these salts from the pancreatic secretion, which contains only a small amount of calcium phosphate, none of the carbonate, and which therefore must be altered in quality by some antecedent affection.

Stagnation of the secretion *per se* cannot be held responsible for the calculi, many cases of complete

obstruction of the pancreatic duct having been observed without their formation, and experimentally, only one investigator (Thirolloix) by the injection of soot succeeded in producing an artificial lithiasis.

As a result of the obstruction of the pancreatic ducts by the calculi the parenchyma suffers, an interlobular pancreatitis occurs, and atrophy of the gland is the result. The acini degenerate and disappear, while the islands remain unaltered until late in the process, when the pancreas, as in several reported cases, is reduced to a fibrous cord with a calculus occluding the duct of Wirsung.

This concludes a very brief and inadequate sketch of the pathology of pancreatitis, time not permitting a more minute description of the lesions in the acute type, nor even mention of the congenital syphilitic form, the interacinar pancreatitis, or bronzed diabetes in the chronic variety.

The surgery of the diseases of the pancreas has been advancing with rapid strides since Senn, in 1886, wrote his classic work. Following upon Fitz's lecture in 1889, upon "Acute Pancreatitis," many contributions

Fig. 4.—Chronic indurative pancreatitis. Fibrous tissue compressing acini and (below and to right) to some extent the island of Langerhans.

have been made to the literature of the subject, and through the splendid achievements in the pathology of this organ a mass of facts and observed symptoms have accumulated, which bid fair to place the pathology and treatment of these lesions upon a sound basis.

At the Congress held in Washington last May, in a symposium upon the diseases of the pancreas, Mikulicz and Park brought the surgery of the pancreas to date, and showed not only the necessity but the wisdom of operating upon pancreatic lesions.

Unfortunately, many points in the etiology and symptomatology of acute pancreatitis are as yet obscure, and obstruct the efforts of the practising physician, who sees but few of these cases, to have them operated upon. The results obtained in the clinical laboratory by examination of the urine, blood, and feces, are not sufficiently definite to enable us to recognize constantly the disturbed metabolic functions coincident upon chronic pancreatitis. Surgical treatment depends upon certain principles, and without intending to transgress upon the field so ably covered by the previous speakers, we must refer casually to certain symptoms furnishing indica-

tions for operation. But first a word in respect to classification. The older one of Fitz, viz., into hemorrhagic, suppurative, and gangrenous, may be classed under the general heading of acute, or in the milder cases, of sub-acute pancreatitis, whether mechanical, toxic, or infectious, but the obscurity of the etiology renders the exact nature of the causal factors difficult to ascertain before operation. The chronic inflammation, with its induration, is divided, as proposed by Opie,⁴ into the interlobular and interacinar forms.

Acute hemorrhagic pancreatitis is sudden in its onset, severe in its clinical manifestations, and remarkably fatal in its termination. Resembling in the early stages an acute intestinal obstruction, or a severe calculous infection of the terminal portion of the common duct, the pain, vomiting, rapid pulse, dyspnea, and cyanosis are followed by collapse, which may be so profound as to presage death a few hours from the beginning of the attack. In other cases the initial shock is not so great, the patient continues to live, suffering from severe epigastric pain, with vomiting, cyanosis, and great weakness. Destruction of the capsule of the pancreas permits the escape of the pancreatic secretion which converts the fat of adjacent areas into a pultaceous mass and speckles the omentum with the wellknown spots of fat necrosis. In one case which we have previously reported,⁵ the lesser cavity was filled with this converted fat admixed with blood, and was of a chocolate color.

Suppurative pancreatitis is believed always to be due to infection. The early symptoms closely resemble the hemorrhagic form, with which, in fact, suppuration may be associated. The actual abscess can rarely be felt in the early stages, and it should be remembered that suppuration may begin in the tail of the pancreas and cause symptoms entirely confined to the upper left side of the abdomen, simulating splenic abscess. Jaundice is often present, and is due to compression of the common duct by the enlarged and swollen pancreas, to the abscess itself, or even to a stone in the common duct—the starting point of the whole process. Pus and blood have been noted in the stools from rupture of the abscess into the duodenum.

Later, an abscess develops in the lesser peritoneum and may appear as an epigastric tumor with the other symptoms of a pus collection. By a fluoroscopic examination the mass may be seen to be separate from the liver and spleen and not movable with the diaphragm.

Gangrene and necrosis of the pancreas present but few symptoms and can hardly be diagnosed, unless portions of the sequestered pancreas are passed with the stool or found at operation, or unless a clear history of the antecedent acute inflammatory and suppurative lesions can be elicited.

The indications for operation in acute pancreatitis are furnished by the pathology of the disease and the history of the cases so far reported. The extraordinary rapidity with which death so often follows, shortly after the onset, makes any delay inadvisable and yet the diagnosis is difficult, the symptoms, both objective and subjective are often so ill defined, that the mortality following operative interference is very high. The time for operation is open to considerable question. Mikulicz collected 9 recoveries out of 46 cases operated upon in the acute stage, while 18 recoveries out of 35 occurred when the operation was performed during the later stages of the disease. But, and his great experience carries weight, he advises early operation, "rationally conducted."

In a case which we have previously reported the symptoms were well marked, but thinking that some delay promised more than an immediate operation, we waited nearly a week, keeping the patient at absolute rest with careful feeding and stimulation. No change whatever in the symptoms was observed and as subsequently seen the progress of necrosis was not checked in the least, nor was any attempt made by nature to localize

the lesion. In many forms of acute pancreatitis the disease appears to be a destructive infiltration of tissues by the ferments often associated with infection, and only in those cases in which local areas of pus produce necrotic foci does the disease limit itself. For this reason, we believe that the early operation, "rationally conducted," as Mikulicz expresses it, will finally give us the better results.

The technic of such an operation varies with the nature of the condition present in the pancreas and its adjacent region. Upon opening the abdomen, fat necrosis, if present, is a symptom of great moment indicating the diffusion of the ferment through the lymphatics, and of course decides the diagnosis. The gallbladder should be palpated for calculi, the association of which with pancreatitis being well known, and if found, one of the possible causes of the pancreatic lesion will be recalled and may be of great advantage later. The common duct should always be explored with the finger and at the same time the condition of the head of the pancreas becomes apparent.

The intestines and surrounding viscera must be protected with gauze pads with great care, when the region of the pancreas may be approached with the minimum risk of infection. The organ may be reached: (1) Through the gastrocolic omentum, below the stomach; (2) through the gastrohepatic omentum above the stomach; (3) through the transverse mesocolon, back of the colon and stomach. The first method is the most applicable for the purpose of drainage and consists in dividing the two layers of the peritoneum forming the gastrocolic omentum, raising the stomach and then cutting through the ascending layer of the transverse mesocolon. The pancreas is then observed and the actual lesion determined. It is well at this point to recall certain points formulated by Mikulicz:

1. The very slight tendency of pancreatic hemorrhage to stop spontaneously.

2. The locally destructive and general toxic action of the pancreatic ferments set free by the inflammatory and hemorrhagic processes, and finally—

3. The ease with which the pancreas may be infected from the ductus choledochus.

That these points are important can be readily understood. Acute hemorrhagic pancreatitis is marked by a diffuse hemorrhage within the organ with disintegration of the pancreatic tissue and erosion of the vessels. Such bleeding is often hard to check, even from small vessels, and may require the extensive use of gauze tampons, or more rarely, the introduction of deep sutures. The latter procedure is rather dangerous from the chance of producing necrosis of the gland, but may be necessitated by a threatened fatal hemorrhage.

The action of the ferment leads to a progressive necrosis of the pancreatic cells, a self digestion, as well as of the surrounding fat. This cannot be checked by operation, but may be prevented to a great extent by free and proper drainage. Finally, infections from the duodenum involving the pancreas require the same treatment as an infected area in any other portion of the body, viz., free incision and drainage.

If, then, the pancreas merely presents a swollen, tense, edematous appearance, reddish or purplish in color, and without marked peripancreatic involvement, an incision should be made in the long axis of the pancreas and extending the entire length of the gland if necessary. Drainage to this opening, though uphill, will sufficiently provide for the serous effusion and broken down cellular products.

When the peripancreatic involvement is severe with great necrosis of the gland and of the fat in the neighborhood of the lesser omentum, loin drainage is required, after free incision of the pancreas. It is useless to attempt to dissect out the necrotic foci. The loin incision is made at the left costovertebral angle.

Abscess, necrosis and gangrene of the pancreas re-

quire identical treatment, viz., incision when necessary, followed by free drainage through the loin.

After completing the technic of the operation about the pancreas and disposing of the drains the area of disease must be carefully walled off from the general peritoneal cavity by gauze. This step in the procedure is materially aided by the supracolic incision, the omentum extending downward and without becoming entangled in the gauze wicks which are above. The toilet of the abdomen is completed and the wound closed as far as possible.

In cases complicated by the presence of stones in the gallbladder or the bile ducts, the operation is considerably complicated, as the incision is too far to the left for the best performance of a cholecystostomy. The mere presence of the calculi presupposes an infection of the biliary ducts, which was probably the factor concerned in the production of the pancreatitis. In such cases removal of the stones and the establishment of an external biliary fistula greatly assist the chances for recovery. When the stone occupies the common duct, especially in its course beneath the head of the pancreas, the greatest ingenuity and operative skill are often required to pre-

Fig. 5.—Chronic atrophic pancreatitis. Island of Langerhans, surrounded by fat, instead of acini.

vent a fatal catastrophe from a subsequent peritonitis by leaking, infected bile. A choledochotomy may be performed if the stone cannot be dislodged or the duodenum opened and the papilla split up, depending upon the exigencies of the case.

The surgery of chronic pancreatitis has been made in recent years, and what was formerly regarded as a hopeless and incurable condition, offers a field which will add a new laurel to the brilliant achievements of latter-day surgery. In 1886, Senn wrote, "that cirrhosis or chronic interstitial pancreatitis sometimes produces stenosis of the bile duct or the pancreatic duct, and that when the obstruction is followed by the retention of the secretions, an operation becomes always necessary in biliary retention, which should be treated by establishing a new outlet for the bile into the duodenum. The formation of an external pancreatic fistula in cases of cyst of the pancreas becomes necessary only when the presence of the swelling in itself has become a source of sufficient pain and discomfort to warrant treatment by abdominal section."

Senn, however, while upon the right path, revealed only half a truth, and we now know that it is not neces-

sary to wait for jaundice to establish a bile fistula. It is principally to Mayo Robson that we owe the impetus given to the surgical treatment of chronic inflammatory enlargements of the head of the pancreas; for while many other surgeons have observed like results, yet Robson, in 1900, published his observations as a collected report.

The diagnosis of chronic pancreatitis is often exceedingly difficult, and is very frequently confused with carcinoma involving the head of the pancreas. In the only fatal case which we have observed after operation for chronic pancreatitis, the diagnosis was believed to be carcinoma, even at the operating table, though at necropsy a marked condition of interlobular pancreatitis was found; no malignancy. Mikulicz had an exactly similar experience. The complexity of the symptomatology in chronic pancreatitis depends upon the associated lesions in the stomach, intestine and liver, where such conditions as gastrointestinal and biliary tract inflammation, arteriosclerosis, alcohol, etc., have been the causal factors in the production of the chronic pancreatitis.

The essential lesions from the standpoint of surgery are:

1. Chronic pancreatitis due to obstruction of the ducts of the glands by biliary or pancreatic calculi.
2. Chronic pancreatitis due to infection, usually secondary to an obstruction of the ducts by gallstones, or by carcinoma, though not necessarily so. Opie⁶ has observed 4 cases in which the clinical history afforded evidence of continued gastric or gastrointestinal disease. They were presumably the consequence of an ascending infection of the duct.
3. The form of the disease arising in consequence of the effects upon the organs of the misuse of alcohol, from arteriosclerosis, endarteritis, syphilis, and general tuberculosis. In these cases biliary cirrhosis and perhaps interstitial nephritis are coexistent.
4. Interacinar pancreatitis, of unknown origin, with disease of the islands of Langerhans, and usually diabetes.

The technic of the surgical treatment of chronic pancreatitis can be dismissed in a few words. The cause of the disease must be removed, if a biliary or pancreatic stone, and temporary or permanent drainage of the bile provided for. The method of making the fistula has caused considerable discussion, most surgeons preferring the external opening, or cholecystostomy. The great advantage of the latter fistula is the ability to keep the drainage constantly under observation. It has been urged that the closure of such a fistula is often difficult, but we find, from our experience, that the nonclosure is always due to the continued existence of an obstruction, either persistent enlargement of the pancreas or a stricture. If such occur after performing cholecystenterostomy or cholecystgastrostomy the liver may become damaged by the infected bile, jaundice supervene, and a dangerous reoperation become necessary.

When the stone is located as being in the ampullas, and the stone cannot be carried back into the common duct, it is best to open the duodenum and slit up the papillas, such a proceeding not requiring any suture to reclose the duct. If the calculus is somewhat to the proximal side of the ampulla of Vater, and cannot be reached by slitting the latter, nor carried up into the duct, a choledochotomy must be performed, after dividing the peritoneum to the outer side of the duodenum and lifting the latter upward. The wound in the duct may be closed by suture, but all of these cases should be drained. With a higher position of the stone, the duct is usually dilated, and the calculus can be pushed up to the cystic duct, and by a choledochotomy removed, and, if not able to carry the stone into the proximal portion of the common duct, the duct may be opened at the site of the stone. In all cases where an infectious cholangitis is present in addition to the pancreatitis, the liver should

be drained by means of a rubber tube introduced into the gallbladder, common or the hepatic duct.

Pancreatitis without stone is frequently completely relieved by a simple cholecystostomy which, by diverting a large amount of bile from the ampulla of Vater, allows better opportunities for the free drainage of the pancreatic secretion.

Chronic pancreatitis with glycosuria and without obstruction of the biliary apparatus may be relieved, to a great extent, by a cholecystostomy, but theoretically an operation offers no hope for cure as the diseased "islands" are not dependent upon any lesion ascending through the ducts.

Cholecystostomy has been referred to several times, and we rarely, at the present time, practise the method whereby the gallbladder is stitched to the aponeurosis and peritoneum. The gallbladder having been aspirated, opened, and any stones or concretions removed, a rubber drainage-tube is introduced for a distance of about 1.5 cm., and fastened by a catgut suture to the edges of the gallbladder wound. The latter are then invaginated inward and a pursestring Lembert suture introduced, holding the rubber tube firmly in position. Gauze drainage is introduced to the subhepatic space beneath the gallbladder, guarding the intestinal side by rubber tissue.

Pancreatic calculi may obstruct the duct of the pancreas and cause permanent injury to the gland, usually in the form of a chronic and atrophic pancreatitis. They are not common, and the great majority of instances noted in the literature have been found at necropsy. The clinical data so far obtained are evidently so insufficient, so inconclusive, that Kinnicutt⁷ in December, 1902, was able to collect but 7 cases, one his own, in which a positive diagnosis of the pancreatic calculi was made or even suspected during life. Moynihan,⁸ however, reported a case diagnosed as chronic pancreatitis and operated upon successfully, removing a stone from the pancreatic duct measuring about 12 mm. by 5 mm. This was the first occasion upon which a pancreatic stone was diagnosed and found by operation. Perhaps the the röntgen ray may aid in making such a diagnosis more frequent in the future.

The operation required in these cases depends upon the location of the stone, and while it may be reached by opening the papilla and duct through the duodenum, yet the operator must be prepared to open the lesser peritoneal cavity and cut down through the gland itself.

The surgery of pancreatic cysts has been well recognized for a long time, and as far back as 1885, Senn wrote a very complete paper, and a year later made the statement that "the treatment by extirpation is not deserving of imitation;" he advocated the formation of an external pancreatic fistula.

The diagnosis of these cysts must be made from renal tumors such as hydronephrosis, from enlarged spleen, ovarian cysts, hydatid cysts of the liver, mesenteric cysts, retroperitoneal sarcoma, and large abdominal aneurysms. The previous history and slow onset, with progressive weakness; the deep situation of the tumor and its slight range of mobility; the condition of the stools; and, further, the fact that the great majority of cystic tumors in the epigastrium are pancreatic, should aid in the diagnosis. Ransohoff,⁹ in July 1901, had collected 159 cases of pancreatic cysts which had been operated upon with a mortality of 7%.

The operative procedure in pancreatic cysts will depend upon the degree of adhesion to surrounding structures, and as this almost invariably occurs, the extirpation of the cyst is difficult unless, as is the case in rare instances, the cyst is pedunculated. In a certain small percentage of cases the cyst can be dissected out. Aspiration of the cyst should only be performed when the patient is severely ill from diabetes or the effects of pressure. The cyst will always refill, and the danger of

leakage into the peritoneum from the point of puncture is very great.

Whenever practicable the abdomen should be opened by a median incision above the umbilicus, and by incising the gastrocolic omentum or the transverse mesocolon the cyst is exposed. Its contents should be withdrawn with an aspirator, as the needle is removed closing the puncture with one or more hemostats. The cyst wall is then drawn to the wound, sutured to the parietal peritoneum, and drained. When the cyst is small, and from its position and relations cannot be brought to the abdominal wound, the rubber drainage-tube should be introduced into the cavity of the cyst, and by careful gauze packing so surrounded that leakage is prevented.

In conclusion, we wish to express our obligations to Fitz, Senn, Opie, Flexner, Oser, Körte, Pierce, Mikulicz, Robson, and Moynihan, and many others, whose writings have stimulated our interest in this fascinating disease.

ON THE OCCURRENCE OF DIABETIC AND NONDIABETIC GLYCOSURIA IN THE SAME INDIVIDUAL.¹

BY

HEINRICH STERN, PH.D., M.D.,

of New York City.

Seven years ago I pointed out² that what we designate as diabetes mellitus is but the second stage of a process of systemic deterioration, that there is a preglycosuric stage of the affection, that the glycosuria is nothing more than the most prominent phenomenon of the second stage of the deterioration, and that the severity of the diabetic state does not depend upon the intensity of the concomitant glycosuria.

Hence, an individual may be diabetic long before glucose has made its appearance in the urine, and he likely continues to be subject to the affection even if for the time being the excretion of sugar is suspended.

Glycosuria is but a consequence, but a manifestation of a variety of causes. It is an enunciation of the diabetic state much in the same manner as it is a symptom of manifold disturbances of either ectogenous or endogenous causation. Its presence does not, a priori, stamp a person a diabetic; on the other hand, its absence in the face of other pertaining phenomena is no conclusive proof of the nonexistence of the diabetic state.

The glycosuric symptom of disease, other than diabetes, is an established fact. It appears and subsides, as its underlying factors supervene or vanish. It may, therefore, be transitory in character, but it may also attain a certain degree of chronicity. Cases of long-continued glycosuria, not modified by a diet free from sugary and starchy substances, are nondiabetic, as a general rule. This is especially the case (excepting, of course, when the patient is in the last stages of diabetes) when progressive bodily decline ensues after a prolonged, unintermitted, antidiabetic regimen.

Apart from the dissimilarity of the clinical pictures of true diabetes and that disturbance of which it forms

an integral part, nondiabetic glycosuria as shown by me¹ differs from the diabetic type in the following respects:

	Nondiabetic Glycosuria.	Diabetic Glycosuria.
Cause.	Demonstrable in most instances.	Unknown.
Duration.	Depending upon nature and degree of underlying factors.	Chronic.
Degree of intensity (uninfluenced.)	Mild, urinary glucose, usually less than 1%.	Higher, urinary glucose from 1% upward.
Amount of urine (uninfluenced.)	Normal, or but slightly (temporarily) increased.	Markedly increased (permanently.)
Nitrogen excreted by urine (uninfluenced.)	Normal ratio.	Increased.
Influence of antidiabetic regimen.	Frequently none or limited. Gerhardt's reaction always negative.	Always. Gerhardt's reaction occasionally positive.
Influence of measures directed toward removal or modification of (known) etiologic substratum.	Frequently positive; cessation or decrease.	

Recalling that in addition to these divergent points of the two general types of glycosuria, the classic symptom-complex of diabetes, including the augmented nitrogen metabolism as described by me,² is either wanting altogether or only partly present in the nondiabetic condition accompanied by glycosuria, and remembering that in the majority of instances a demonstrable cause stands at the foundation of nondiabetic glycosuria, it is not a difficult task to discriminate clinically between the diabetic and nondiabetic forms of melituria.

On the hand of these discrepant factors the occurrence of diabetic and nondiabetic glycosuria in one and the same individual may be recognized. We know that simple glycosuria is not infrequently superseded by well authenticated diabetes. In these cases, however, there is no contemporaneous or alternate, but a successive occurrence of both types of melituria in the manner that the one subsides and the other consequential to the graver condition becomes firmly and permanently established. Such instances, of course, do not belong to the domain of duplex melituria, a term by which I shall designate hereafter the synchronous or alternate occurrence of diabetic and nondiabetic glycosuria.

I have met at least 16 or 17 cases of duplex melituria, upon a study of which are founded the following data and deductions:

Duplex melituria, as the name implies, is always of contemporaneous nature. Clinically, however, it is demonstrable only by the temporary abatement of one pertaining set of symptoms. It is characteristic of the affections that the syndrome subsiding rapidly, even if but temporarily, upon the institution of a rigid antidiabetic regimen, is the one of diabetes. Hence it is mostly by the temporary decrease or cessation of the diabetic phenomenon that the manifestations of an accompanying or intercurrent disorder, plus its glycosuric symptom, become evident or more conspicuous. The recognition of duplex melituria depends, therefore, on the alternate prominence of one set of symptoms, including the respective glycosuria.

If the nondiabetic glycosuria disperses simultaneously with the diabetic melituria, it can hardly ever be recognized. Duplex melituria is just as much a simple glycosuria aggravated by the glycosuric symptom of diabetes, as it is a complication of the latter with simple glycosuria. The two types of glycosuria may be interdependent; in the majority of cases, however, they seem to occur independently of each other. They may be of synchronous production, for which, however, there

¹ Read at the meeting of the Medical Society of the State of New York, January 26, 1904.

is no proof; viewed from the clinical standpoint, one type of glycosuria antedates the other, as the symptom-complex connected with the one always overshadows the syndrome, of which the other is an important factor.

Duplex melituria is the result of two concurrent or intercurrent affections of dissimilar character, having the one symptom, glycosuria, in common. There is no reason why glycosuria cannot reflect two pathologic conditions at any one time, as

CASE 1.

Delineation of duplex melituria. Dotted line shows limit of nondiabetic glycosuria.

does for instance the symptom, fever. The extent to which each type of glycosuria contributes toward the duplex melituria can only be determined by the abatement of one type; as a general rule, however, diabetic glycosuria, as already pointed out, surpasses the nondiabetic form in intensity. A patient, for instance, exhibiting all the clinical phenomena of diabetes, excretes diurnally 3,000 cc. of urine containing 3%, that is 90 gm., of carbamid and 5%, that is, 150 gm., of glucose. After pursuing a strict antidiabetic dietary for four weeks, all the manifestations of diabetes have subsided, the daily amount of urine is reduced to 1,500 cc.; the carbamid, notwithstanding the increased ingestion of proteid material, has not been augmented, which in reality means a decided reduction, but the patient continues to excrete 0.33% glucose, that is 4.95 gm., daily. This amount, in all likelihood, represents the glucose of nondiabetic production. Of course, in far advanced diabetes, a similar differentiation between the two great types of glycosuria cannot be attempted. Here the diabetic glucose—in spite of all dietary regulations—is as enduring as are the other manifestations of the diabetic state.

In uncomplicated diabetes, as long as it has not entered into its last stage, when it is *eo ipso* a complicated affection, the decrease of the glycosuria when under a specific diet, goes as a rule hand in hand with the obliteration of the other diabetic manifestations. The majority of cases of diabetes in which on prolonged dieting the *total* syndrome, save a slight glycosuria, disappears, are, it seems, complicated with disorders of which this very glycosuric condition is the consequence. This is especially the case when the patient, still under a strict regimen, continues to decline after the suppression of the symptom-group of diabetes.

In uncomplicated diabetes, systemic decline is not only arrested after the temporary abatement of the glycosuric and the other pertaining phenomena, but the patient frequently gains in weight and strength even if

the monotonous, though sufficient proteid-fat nourishment be continued for long periods.

Moreover, in diabetic urine, acetone and diacetic acid may occur in excess and betaoxybutyric acid even may make its appearance after prolonged dieting; in nondiabetic glycosuria, while the diet exerts but limited influence upon the excretion of glucose, I have never observed undue amounts of acetone or diacetic acid, nor could I ever detect the presence of betaoxybutyric acid which, in its clinical importance, is a much overrated factor.

For purposes of illustration I have selected a few of my cases of duplex melituria whose pertaining, though abbreviated, histories are related in the following:

CASE I.—Rosa N., aged 53, was born in Russia, and is the mother of 10 children. The patient, according to her physician, exhibited the symptoms of diabetes for the past 18 months. Urine varying from 2,800 cc. to 3,500 cc. per day. Glucose between 3% and 5.5%. She had been on a liberal diet.

The patient was first seen May 17, 1902. She complained of polydipsia, pruritus, weakness, and emaciation. She had lost about 25 pounds since the onset of the disease. Present weight, 151 pounds. She had been repeatedly affected with furunculosis during the past 18 months. No lues.

The physical examination revealed nothing beyond the usual manifestation of progressive emaciation; flabby abdomen, flaccid muscles, enteroptosis and prolapsed right kidney; thoracic and abdominal organs were apparently in fair condition.

Urine, amount for 24 hours, 3,840 cc.; specific gravity, 1.029; acidity, 0.45°; carbamid, 2.9% or 111.36 gm.; glucose, 3.33% or 127.872 gm.; no acetone or diacetic acid. There was no evidence of kidney disease.

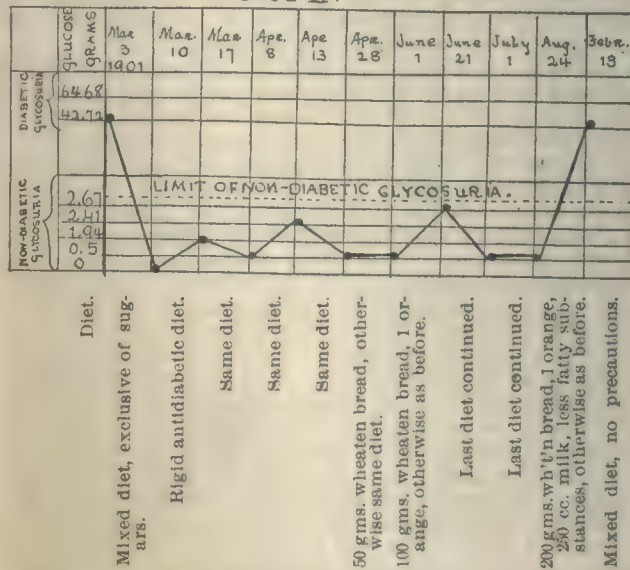

Treatment.—Dietary, exclusion of all farinaceous material and substitution thereof of hydrocarbons—35 calories per day and kilogram of body-weight.

May 24. Body-weight, 152½ pounds. Polydipsia disappeared, weakness less pronounced, pruritus absent. Twenty-four hours' urine, 1,700 cc.; specific gravity, 1.021; acidity, 0.48°; carbamid, 3% or 51 gm.; glucose, 0.10% or 1.7 gm.; acetone and diacetic acid absent. Diet continued.

May 31. Body-weight, 154½ pounds. Diabetic symptoms dispersed, some weakness and glycosuria. Twenty-four hours' urine, 1,600 cc.; specific gravity, 1.0165; acidity, 0.41°; carbamid, 2.6% or 41.6 gm.; glucose, 0.14% or 2.24 gm. No acetone or diacetic acid. Diet continued.

June 14. Body-weight, 159 pounds. Twenty-four hours' urine, 1,450 cc.; specific gravity, 1.0155; acidity, 0.40°; car-

CASE II.

Delineation of duplex melituria.

amid, 2.2% or 31.90 gm.; glucose, 0.14% or 2.03 gm. Diet continued.

June 22. Body-weight, 161 pounds. Patient complained of irritability and insomnia. The urine exhibited the same features as on the 3 previous occasions; amount of excreted glucose still above 2 gm. in 24 hours. All the phenomena of diabetes have vanished. Patient continued to gain in weight. Irritability and other nervous phenomena not due to subali-

mentation. Diet: 100 gm. of wheaten bread (toasted) per day in addition to the former dietary.

June 28. No diabetic symptoms. Irritability and insomnia continue. Body-weight, 160 pounds. Glucose output, 1.75 gm. in 24 hours. Diet: 150 gm. of wheaten bread (toasted) per day, 300 cc. of milk in divided portions, proteid material, less fatty substances. Total caloric value, about 35 per day and kilogram of body-weight.

July 5. Body-weight, 160½ pounds. No diabetic symptoms. Irritability and insomnia continue. Glucose output, 1.9 grams. Diet: Farinaceous material *ad libitum*.

July 11. Polydipsia and pruritus returned; irritability and insomnia have yielded to weakness and languor. Body-weight, 158½ pounds. Twenty-four hours' urine, 3,100 cc.; carbamid, 2.8%, or 86.8 gm.; glucose, 3.8%, or 117.8 gm. Diet: Rigidly antidiabetic.

July 21. Body-weight, 158 pounds. Diabetic phenomena disappeared again. Irritability and insomnia returned, feels stronger. Twenty-four hours' urine, 1,800 cc.; carbamid, 3%, or 54 gm.; glucose, 0.16%, or 2.88 gm. Diet: Strictly antidiabetic.

August 16. Body-weight, 160½ pounds. Diabetic manifestations absent; irritability and insomnia persisting; fairly strong. Twenty-four hours' urine, 1,480 cc.; carbamid, 3.1%, or 45.88 gm.; glucose, 0.14%, or 2,072 gm.

Treatment.—Medicinal for neurotic condition.

Dietary.—Allowance of carbohydrates to the extent that not more than 3 gm. of glucose are excreted daily. Patient has in the course of time ingested as much as 250 gm. of bread, 500 cc. of milk, and one apple or orange per day, without superintention of diabetic glycosuria or any of the other symptoms of diabetes.

CASE II.—William A., aged 50, native of United States, lawyer.

Patient, according to the notes of his physician, had been affected with typical diabetes for almost 2 years, when he came under my observation. The daily urine amounted to about 2,500 cc. on the average; the glucose output varied between 2% and 4%. Had been for occasional short periods on a somewhat restricted diet, but never under a rigid antidiabetic regimen. For the greater part of the time the only dietary restriction consisted in the exclusion of sugars.

The patient was first seen March 3, 1901. He stated that he was affected with nocturnal polyuria, loss of memory, and weakness, and that he had lost about 30 pounds since the onset of the disease. Present weight, 177½ pounds. No lues.

The physical examination evidenced a somewhat enlarged liver, slight gastrectasis, and a somewhat irritated heart. The other organs were apparently in a normal state.

Urine.—Amount for 24 hours, 2,200 cc.; specific gravity, 1.026.5; acidity, 0.52°; carbamid, 2.3%, or 50.6 gm.; glucose, 2.94%, or 64.08 gm. No acetone or diacetic acid; no evidence of renal disease.

Treatment.—Rigid antidiabetic diet, 35 calories per day and kilogram of body-weight.

March 10. Body-weight, 178½ pounds. Nocturnal polyuria almost disappeared; memory about the same, feels stronger. Twenty-four hours' urine, 1,550 cc., specific gravity, 1.020; acidity, 0.53°; carbamid, 2.6%, or 40.30 gm.; glucose, none; acetone and diacetic acid, none; other foreign substances, none. Diet continued.

March 17. Body-weight, 179½ pounds. Nocturnal polyuria subsided entirely; memory improved; feels decidedly stronger. Twenty-four hours' urine, 1,550 cc.; specific gravity, 1.020; acidity, 0.50°; carbamid, 2.5%, or 38.75 gm.; glucose, 0.125%, or 1.94 gm.; no acetone or diacetic acid. Diet continued.

April 8. Body-weight, 180½ pounds. Feels very well. Twenty-four hours' urine, 1,650 cc.; specific gravity, 1.019; carbamid, 2.2%, or 36.30 gm.; glucose less than 0.5 gm. Diet continued.

April 13. Body-weight, 181½ pounds. Constipated, flatulence, headache. Twenty-four hours' urine, 1,725 cc.; specific gravity, 1.020, glucose, 0.14% or 2.41 gm.

Treatment.—Fifty grams wheaten bread daily in addition to former diet; medicinally for the inactivity of the liver, fluid extract of chionanthus virginica.

April 28. Body-weight, 182 pounds. Abdominal symptoms and headache disappeared a few days ago. Twenty-four hours' urine, 1,500 cc.; specific gravity, 1.019.5; glucose less than 0.5 gm.

Treatment.—Diet: 100 gm. wheaten bread, 1 orange, otherwise as before.

June 1. Body-weight, 183½ pounds. Feels well. Specific gravity, 1.018; glucose less than 0.5 gm. Diet as before.

June 21. Nausea and vomiting, constipation and flatulence. Twenty-four hours' urine, 1,675 cc.; glucose, 0.16%, or 2.67 gm. Diet as before.

July 1. Body-weight, 182½ pounds. Feels well. Glucose less than 0.5 gm. Diet: 200 gm. wheaten bread, 1 orange, 250 cc. milk, less fatty substances, otherwise as before.

August 24. Feels well. Glucose less than 0.5 gm. Patient continued for some time in a very good condition, always excreting small amounts of glucose. Some months afterward he discarded all dietary precautions.

February 13, 1902. Reappearance of diabetic phenomena. Body-weight, 180 pounds. Urine, 2,400 cc.; specific gravity, 1.025.5; carbamid, 2.4%, or 57.6 gm.; glucose, 1.78%, or 42.72 gm.

CASE III.—Louise C., aged 58, native of United States, widow, no children.

Patient had been affected with a parotid abscess involving the adjacent lymphatic gland. Nothing short of a parotidectomy, performed during the winter of 1898-1899, gave relief to the local symptoms. Almost immediately after removal of the parotid the patient's sense of hearing became impaired, she began to suffer from headaches and attacks of indigestion, and a slight glycosuria—never higher than 0.75%—of more or less chronicity, supervened.

According to the statement of her physician, phenomena characteristic of diabetes were not exhibited until the following September, when an analysis made at a public laboratory showed the urine to possess a specific gravity of 1.032 and to contain carbamid 0.9% and glucose 4.4%. No evidence of renal disease was demonstrated.

Patient was first seen November 18, 1899. She stated that her deafness became more pronounced from day to day, that she had intense pruritus of the vulva since about the middle of September, that she had great thirst and that she must urinate frequently. Had lost considerably in weight, "at least 4 inches

CASE III.

Delineation of duplex melituria.

in bust measure" during the past two months. Present weight 161 pounds. No lues. Suffered occasionally from dull headache at the base of brain. Had indulged in all kinds of food, including sweets.

The physical examination revealed a very weak heart, in the condition of fatty degeneration, a state of general arteriosclerosis, enteroptosis, distended stomach, some coprostasis, and very flaccid muscles.

Urine.—Amount for 24 hours, 2,800 cc.; specific gravity, 1.024; acidity, 0.55°; carbamid, 2%, or 56 gm.; glucose, 3.1%, or 86.8 gm. No acetone or diacetic acid. No characteristics of kidney disease. Rigid antidiabetic diet in any desired amount.

November 28. Body-weight, 155.5 pounds. Feels much improved. Loss of weight very likely due to incessant diarrhea since institution of proteid-fat nourishment; thirst moderate, some insomnia. Twenty-four hours' urine, 2,250 cc.; specific gravity, 1.018.5; glucose, 0.38%, or 8.55 gm. Antidiabetic diet as before. Antidiarrheal medication.

December 7. Body-weight, 159 pounds. Deafness continues, otherwise improvement very marked; muscles appear harder; seems to have her old spirits and energy. Twenty-four hours' urine, 1,800 cc.; specific gravity, 1.019; glucose, 0.55%, or 9.90 gm. Diet as before.

December 14. Body-weight, 160½ pounds. Deafness unchanged; improvement continues. Twenty-four hours' urine, 1,825 cc.; specific gravity, 1.022; glucose, 0.58%, or 10.56 gm. Diet as before.

January 13, 1900. Body-weight, 164 pounds. Deafness permanent; feels very well. Twenty-four hours' urine, 2,100 cc.; specific gravity, 1.015; glucose, 0.43%, or 9.03 gm. Diet: mixed food, including 300 gm. carbohydrates and 250 cc. milk.

February 21. Body-weight, 171 pounds. Feels well, excepting the occasional dull pain at the base of the brain. Twenty-four hours' urine, 1,560 cc.; specific gravity, 1.017.5; glucose, 0.51%, or 7.96 gm. Diet somewhat restricted, as before.

The foregoing 3 cases are typical instances of duplex melituria. The differences in these 3 cases are multiplex, but they all have in common a condition of true diabetes plus another disorder also characterized by a more or less pronounced glycosuria tending to chronicity. The additional disorder exhibiting a glycosuria symptom in Case I is undoubtedly one of the central nervous system; in Case II it is the enlarged liver and its perverted activity, and in Case III it is the loss of the parotid gland implying the probable loss of an internal secretion, which stand at the foundation of the nondiabetic glycosuria.

In Cases I and II, diabetes may have been the original affection; in Case III the glycosuria antedated the occurrence of diabetes without any doubt. In all the cases the body-weight increased on the institution of a rigid dietary as long as the organism was in an actual diabetic condition; the moment the diabetes resumed its latent character and the phenomena of the concurrent affection appeared in the foreground, the restricted diet remained without any decided influence upon the absolute body-weight. Excepting on one occasion in Case II, all the dietary restrictions could not completely suppress the low, accompanying glycosuria. That this was in no instance due to the synchronous diabetic condition is proved by the rapid disappearance of all the diabetes phenomena on the institution of the strict diet. The diabetic affections in the 3 cases were of an exceedingly mild nature; in 7 days' dieting the daily glucose output in Case I was reduced from 128 gm. to 1.75 gm; in the same period of time the glucose excretion in Case II amounting to 64.68 gm. in 24 hours, had entirely disappeared, and a reduction from 86.8 gm. to 8.55 gm. per day ensued in Case III, within 10 days.

That the accompanying low degree of glycosuria in the 3 cases was not diabetic in character is evidenced: 1. By its continuation after the rapid suppression of the manifestations of a mild diabetes. 2. By its persistence after prolonged and rigid antidiabetic dieting. 3. By the increase in body-weight in spite of the persistence of the glycosuria. 4. By the normal, or almost normal amount of urine eliminated after disappearance of the high degree of glycosuria. 5. By the excretion of proportional small amounts of carbamid during the continued ingestion of large quantities of nitrogenous substances. 6. By the greater prominence of certain, more than transitory phenomena, after the establishment of the artificial latency of the diabetic state.

One could adduce that the low degree of glycosuria was nothing else but the insuppressible portion of the diabetic glycosuria. To this must be remarked that the nondiabetic glycosuria not only antedated the diabetic glycosuria and continued in unaltered form after subsidence of the diabetic manifestations in one of the cases, but that the diabetic phenomena were of a type readily and completely responding to dietary measures, of a type in which the excreted glucose is the result of perverted amylolysis only.

That the concomitant low degree of glycosuria was not the consequence of proteolysis or of plasmolysis,* indicating the graver and the gravest diabetic states, respectively, is peremptorily precluded by the progressive gain in weight and the associated diminished egestion of nitrogenous material after subsidence of the demonstrable diabetic phenomena.

The following points may be deduced from this communication:

1. The diabetic state may be well established before glucose is excreted by the urine. Diabetic glycosuria is nothing more than the salient feature of the second stage of the diabetic deterioration.

2. Glycosuria is a symptom, an enunciation of manifold other disturbances of ectogenous, as well as of endogenous causation.

3. With the assistance of various discrepant factors we are enabled to differentiate clinically between the diabetic and nondiabetic form of glycosuria.

4. Duplex melituria is the result of two concurrent or intercurrent affections of dissimilar character, having the one symptom, glycosuria, in common.

5. The recognition of duplex melituria depends on the alternate prominence of one set of symptoms, including the respective glycosuria.

REMARKS ON THE UNCINATE GROUP OF FITS, AND ON SEVERE SUBCUTANEOUS HEMORRHAGE OCCURRING IN EPILEPSY.¹

BY

WILLIAM G. SPILLER, M.D.,
of Philadelphia.

Associate Professor of Neurology, and Professor of Neuropathology in the University of Pennsylvania.

Certain movements of the mouth and tongue, tasting movements, occurring in epilepsy have been described repeatedly by Hughlings Jackson, and have been regarded by him as the result of an epileptic discharge, beginning in the gustatory elements of a certain region of the cerebral cortex (taste region of Ferrier.)

Hughlings Jackson says:

"... he who neglects the 'dreamy state,' because it is indefinite and 'merely curious,' and such symptoms as chewing, etc., movements, and apparent alteration in the size and distance of external objects, because they seem trifling things, may not even surmise that his patient has the serious disease, epilepsy, in a rudimentary form, until a severe fit comes to tell him so."

In another place he says:

"I have ... suggested for these cases the name of uncinat group of fits; this was on the hypothesis that the discharge lesions in these cases are made up of some cells, not of the uncinat gyrus alone, but of some cells of different parts of a region of which this gyrus is part—a very vague circumscription, I admit—the uncinat region. In cases of this group there is at the onset of the paroxysms a crude sensation of smell or one of taste, or there are movements of chewing, smacking of the lips, etc., (sometimes there is spitting). In some cases of this group there is a warning by what is known as the epigastric sensation, a crude development of a systemic sensation; this warning sometimes occurs along with a crude sensation of smell or with the chewing, etc., movements. Different varieties of this group of cases depend, I suppose, on discharge lesions of different parts of what I call the uncinat region.

There is, according to Hughlings Jackson, a dreamy state in the paroxysms of many—not of all—cases of the uncinat group of epileptic fits, or the dreamy state may occur without any of the crude sensations mentioned.

I can, perhaps, illustrate best what is meant by the dreamy state, by referring to the condition in one of Hughlings Jackson's patients. The man felt "as if he were saying, doing, and looking at things which he had experienced before." "Surrounding people seemed to have strange expressions on their faces, and people and things seemed to be far away." The dreamy state or intellectual aura varies very much in different cases, there may also be fear or a sense of impending death.

The symptomatology of uncinat fits refers especially to the digestive system.

Hughlings Jackson speaks more especially of chewing and tasting movements, but probably he would class swallowing movements among his uncinat group of fits, and indeed, he refers to a case reported by Herpin in which during the attacks there were sounds of deglutition, and the attacks were regarded by Hughlings Jackson as of the uncinat variety.

Jackson is inclined to include in the uncinat group of fits the asphyxia occurring in slight attacks, the "turning blue," and explains this asphyxia by the fact

* Employed here to designate disintegration of body albumin.

¹ Read before the section on General Medicine of the College of Physicians of Philadelphia, February 8, 1904.

that respiration can be slowed and arrested in animals, as shown by W. G. Spencer, by irritation of a certain spot situated to the outer side of the olfactory tract just in front of the junction of the tract with the uncinate.

Purves Stewart has been able to collect 6 cases with necropsy, reported in the literature, in which some lesion of the temporosphenoidal lobe was the cause of the uncinate group of fits.

I have had a few clinical cases that probably should be regarded as of the uncinate type, and I report them because of the importance of the recognition of this group of cases, and as a contribution to the study of cerebral localization, especially of localization in a region of the brain which has been regarded as almost a "silent" area.

A. E. T., female, single, aged 27; is unable to give an account of her family. She had her first attack when 3 years of age, and has had attacks as often as once or twice daily. When the attack is coming on she sees a bright light in front of her, objects appear strange and out of place; sometimes they are large and sometimes small, and she has the taste of raw, unsalted beef in her mouth. She then loses consciousness. Her mother says she has convulsive movements, bites her tongue, and has involuntary passage of urine. The patient passes into sleep after the attack is over.

W. McG., female, married, aged 29, is unable to give any history of epilepsy in her family. Her first attack occurred when she was about 28. It began with a creeping sensation in her left upper limb, which seemed to ascend the limb gradually and to involve the left side of the tongue, so that the tongue felt thick. She then was obliged to sit down and seemed to be unconscious, although she heard all that was said to her, but she could not speak. She saw everything about her during the attack, but vision was blurred. She had a "gassy taste" at the time of the attack. She has had 3 of these attacks, but she has never fallen, and has not had convulsive movements, nor involuntary micturition. She has dreams, in which she imagines she is being killed.

C. S. was a patient of Dr. J. H. Musser and was seen by me September 18, 1903. The notes taken at that time are as follows: The man, aged 40, is married and has 8 children; none of these has had teething spasms. One child had convulsions during an attack of whoopingcough, and another child had convulsions after eating raw lima beans. No history of epilepsy in the family can be obtained. The patient denies syphilitic infection, says he has never had any venereal disease, that he never drank heavily and stopped drinking entirely 9 years ago. He has not smoked during the past 2 years, but smoked much before that time. He says he has had hyaline and granular casts and albumin in his urine. He has no cardiac disease. He has always been nervous, easily annoyed and made to tremble, and cries from little cause. During the past 2 years he has had occasionally what his wife calls "swallowing spells," and in these he would become unconscious, make the noise and movement of swallowing, and rub his fingers together. These attacks last a minute or two. Otherwise the patient was healthy until April 29, 1903. He has had very little headache.

On April 29, 1903, he had a severe convulsion at 6 a.m. The convulsive movements implicated both the upper and the lower limbs, but did not appear to be severe enough to injure him, and were as severe in one upper limb as in the other, but were more intense in the lower limbs. He was unconscious during the attack. When he regained consciousness the right upper limb was completely paralyzed and exceedingly painful. After about 3 weeks he began to regain power in the right upper limb. The left upper limb was not affected after the convulsion for about 2 weeks, then as the right upper limb improved the left upper limb became weak, and pain was felt in this left limb on movement, but very little pain was felt when the limb was kept still. He regained full power in the right upper limb. After the first convulsion he had subcutaneous hemorrhages in the conjunctiva, in the face and about the right shoulder. The hemorrhages in the face were punctate.

The second convulsion occurred July 14, 1903, and was not so severe as the first. It began with swallowing movements. The right upper limb became completely paralyzed after this attack and exceedingly painful. The left upper limb was stiff, but not more paralyzed than it is at the present time. Pain in the left upper limb was still felt only on motion. The voluntary power partially increased in the right upper limb. After the second attack the man had severe hemorrhages in the right side of the neck, right shoulder, and right upper limb, and sensation was lost in the thumb and in the first finger of the right hand.

A third attack occurred a little over a week ago. At the present time (September, 1903) he has extensive subcutaneous hemorrhage in the right upper limb above the elbow. He can shrug the right shoulder, but cannot raise the right upper limb at the shoulder at all. He can flex the right forearm on the arm. The grasp of the right hand is very feeble and he complains of a sensation of numbness in this hand. Sensation for

touch and pain is normal in the upper limbs. No distinct atrophy of the upper limbs is found. He can raise the left upper limb, but not to a right angle with the shoulder, and the backward and forward movements are limited. He has normal movement at the left elbow and in all parts below this in the left upper limb. The grasp of the left hand is impaired, but is much better than that of the right hand. He has not struck his shoulder at any time. He seems to have ankylosis of the left shoulder. The biceps tendon jerk is very much diminished in the right upper limb, but the triceps tendon jerk is prompt. The biceps tendon and triceps tendon reflexes and wrist reflexes are much exaggerated on the left side. The voluntary power in the lower limbs is normal. The patellar reflexes are exaggerated. Ankle-clonus is not obtained. The achilles reflex is normal on each side. Babinski's reflex is not present on either side.

Between the second and third convulsive attacks he had 5 "swallowing spells," as his wife calls them.

The "swallowing spells" preceded any convulsive attack about a year and a half, and the case probably belongs to the uncinate group of fits, although his wife says that the patient does not get blue in the face during his swallowing spells, that he has no peculiar taste in the mouth, that he has no chewing or spitting movements with the "swallowing spells," and does not smack the lips, and that he is unconscious during the "swallowing spells," although occasionally he will answer questions. Inasmuch as one of these attacks has never been seen by a thoroughly trained observer, the statements of the wife may be inaccurate.

Especially interesting is the occurrence of the severe subcutaneous hemorrhages in the face and right upper limb. Evidently neuritis of the right upper limb was caused by this intense outpouring of blood about the brachial plexus, and the ankylosis or arthritis of the left shoulder was the result of the convulsive movements. It seems probable that arthritis was started by hemorrhage. The case in this respect is very uncommon.

We have in this case extensive organic changes produced by the epileptic attacks, and it is reasonable to suppose that similar lesions may occur in rare cases within the brain during epileptic attacks. This seems to be shown by the following case, which I report, as we are so prone to regard every cerebral lesion found in a case of epilepsy as the cause of the convulsive attacks, forgetting that some of the lesions may be the result of such attacks.

T. A., male, aged 16, had his first attack when 8 years old. He has had numerous severe convulsions. When 15, he had status epilepticus, and was unconscious 8 hours. His entire right side was then found to be paralyzed. Speech was lost about a month. When he was examined at the age of 16, the muscles of the right side were spastic, the gait was somewhat stiff, the grip of the right hand was good, and there was still some motor aphasia.

This boy had had numerous convulsions. It seems probable that during the status epilepticus a lesion of the brain developed, possibly hemorrhage or thrombosis, and caused the persisting symptoms in the right limbs, and the disturbance of speech.

Tuberculosis Decreases in Germany.—An exchange says: In a period of 25 years the relative mortality from tuberculosis in Germany has decreased 139, or 39%, per 10,000 of population. If the discovery of Prof. Koch has not accomplished all that was hoped for from it in the way of completely getting rid of tuberculosis in Germany, other methods and treatment are doing gradually what he expected to do immediately. At the present rate of improvement a century will see tuberculosis almost entirely rooted out in Germany, and in a generation it will be reduced to one of the minor diseases in the number of deaths caused by it.

Yellow Fever Experts go to Panama.—Information from Washington, D. C., on March 3, says: Having acquired the right of way for the Panama Canal, the United States now proposes vigorously to take steps looking to the protection from malaria and yellow fever of the large number of Americans who undoubtedly will be attracted to that section when the work of construction begins. It has been decided to bring Colonel W. C. Gorgas, the yellow fever expert of the army, to Washington for a conference with Admiral Walker. Dr. Gorgas is an immune, and will go to the Isthmus prepared to put into execution the methods adopted by him in Havana, which brought such effective result.

REFLEX CARDIAC INHIBITION RESULTING FROM IRRITATION OF THE PERIPHERAL FIBERS OF THE TRIFACIAL NERVE AND OCCURRING IN THE COURSE OF AN OPERATION FOR CHRONIC EMPYEMA OF THE FRONTAL SINUS.¹

BY

GEORGE FETTEROLF, A.B., M.D.,

of Philadelphia.

In the course of operations on the upper air passages, in regions supplied by the terminal fibers of the fifth cranial nerve, I have at times noted an embarrassment of

the circulatory apparatus which was entirely out of proportion to the severity of the operation or the general condition of the patient. It was not until the patient, whose case is herewith reported, came to the table that the true inwardness of the situation occurred to me, and on looking up the literature of the subject and working out an explanation of

Showing slight scarring of operation.

the phenomenon, I elicited several points which should prove to be of practical as well as of scientific interest to those working in rhinolaryngologic fields.

The patient is a vigorous working man of 35 and a caulker by occupation. His family history is negative as far as his nasal condition is concerned, his father being alive and healthy at the age of 75, his mother having died from a gastric tumor at the age of 35, and his only brother having been killed at the age of 40. As a child he had measles and mumps and 13 years ago had a severe attack of inflammatory rheumatism which left his heart unimpaired.

His more recent personal history is of decided interest, since during the last 5 years he has had 3 severe blows over the bridge of his nose and right frontal sinus, the first by a baseball 5 years ago and the others by pieces of timber 4 and 2 years ago. Following the first of these injuries he suffered considerable supraorbital pain, associated with a great deal of hemorrhage and nasal obstruction. From this on he was never free for any length of time from a sense of fullness, throbbing and supraorbital pressure, associated with which was a feeling of exophthalmos. These attacks became longer and longer in duration and the intervals increasingly short. Winter before last he came to my clinic at the Methodist Hospital and I gave him only palliative treatment, as his condition then did not warrant external operation. The ideal procedure at that time would have been the conventional one of removing the anterior half of the middle turbinal, but his septum was so far deflected to the right that this was impossible and a straightening operation was out of the question because the nasal irritation was too great to allow of even a brief retention of any form of splint. After attending the clinic for a few weeks he disappeared and I saw nothing of him until the latter end of last February, when he returned with the old train of symptoms. At this time the middle turbinal was very much inflamed and there was a large polypus depending from its inner surface near the hiatus semilunaris. Removal of this failing to give him any relief, I had him admitted to the house and put to bed. He was suffering intense pain over the right eye, his upper lid could hardly be raised, and there was distinct bulging of the supraorbital area. In addition, the power of hearing in his right ear was becoming impaired. For a week his nose was sprayed with a warm alkaline solution of suprarenal gland and cocaine, followed by a bland oil. Cold compresses, changed every 10 minutes, were used externally. He had a daily remission of his symptoms in the morning, but they would return in all their severity in the evening. Palliative treatment having availed nothing, I determined to operate.

The patient was prepared in the morning by shaving his moustache and eyebrows, and his scalp as far back as the coronal suture. Just before the operation his conjunctival sac was cleansed with boric acid solution, and his forehead and face with mercuric chlorid solution and alcohol. The area of operation was covered with a sterile dressing, which was allowed to remain in place until anesthesia was complete. The external incision began at the junction of the outer and middle thirds of the eyebrow and terminated over the lower margin of the glabella. The soft tissues and periosteum were retracted, and a button of bone removed with a $\frac{3}{8}$ -inch trephine. As soon as the edge of the trephine entered the sinus, and before the button was completely severed, seropus and flakes of lymph exuded from the wound. As the opening after the removal of the button was not sufficiently large to permit of thorough cureting of the sinus, it was enlarged upward and outward with rongeur forceps, care being taken to keep the supraorbital margin intact. The mucous membrane was found to be covered with foul-smelling granulation tissue and pus, which was especially thick at the entrance to the infundibulum. This was cureted away until the entire bony wall of the sinus was exposed. There were no spots of caries in the walls, nor was there any communication with the sinus of the opposite side. The probe passed freely into the nose without eliciting any suggestion of caries, and in the absence of a Panas' probe an ordinary silver one was introduced into the infundibulum, and brought out of the anterior naris. This was moved backward and forward a number of times, and the passage way thus made patulous. The cavity was syringed freely with hydrogen dioxide until froth ceased to come from either sinus or nose, and then douched with hot boric acid and permanganate solutions. After thorough drying, the whole interior of the sinus was swabbed with 50% zinc chlorid solution, and again douched. The cavity was then packed with acetanilid gauze, and the outer two-thirds of the wound closed with interrupted silk sutures, the inner third being allowed to remain open for the purposes of packing and douching. An ordinary sterile dressing was applied, the eye being covered with a disc of gauze dipped in boric acid solution, and the hollow at the inner canthus filled with cotton.

The interesting feature of the operation was the occurrence of a trigemino-cardioinhibitory reflex. Each time the curet would be applied to the sinus wall there would be a marked diminution in the force, fullness, and frequency of the pulse, along with distinct cyanosis. The cureting had therefore to be frequently interrupted. This phenomenon has occasionally been noted in operations involving areas supplied by the fifth nerve, and especially by dentists. One of my assistants told me that he frequently anesthetized for dentists, and when chloroform was the anesthetic used had so often noted cardiac embarrassment at the instant of the extraction of the tooth that he had become quite timid about giving an anesthetic for any dental operation. The particular area of the fifth nerve involved in the case just described was, of course, the mucosa of the sinus. In none of the standard textbooks on anatomy have I been able to find any description of the nerve supply of this region. It must unquestionably be from the trifacial and examination of a number of skulls leads me to the belief that the principal source is from the supraorbital, with possibly additional filaments from the nasal and the malar branch of the temporomalar.

That this reflex does occur has been proved experimentally by Brodie and Russell,¹ who among their conclusions state the following: "The connection of the respiratory tract with the cardioinhibitory center is very close. Thus, stimulation of the nasal mucous membrane at once arrests the heart. Stimulation of the laryngeal mucous membrane is only a little less effective. Stimulation of the trachea and large bronchi is apparently without effect, but stimulation of the alveolar nerves is about as effective as that of the laryngeal. These nerves produce the result when stimulated electrically in their course from the mucous membrane, or when stimulated electrically or mechanically in the mucous membrane itself." The path of the impulse is clear. It runs through the afferent fibers of the fifth to the Gasserian ganglion, then through the fibers of the sensory root to the deep origin which comprises the sensory nuclei in the floor of the fourth ventricle and the gray substance of the substantia gelatinosa of Rolando as far down as the second cervical nerve. From these situations the path to the nucleus ambiguus, which contains the motor

¹ Read at the annual meeting of the Eastern Section of the American Laryngological, Rhinological and Otological Society, held at Fall River, Mass., January 30, 1904.

centers of the vagus, is short and direct, and is probably through some of the fibers of the posterior longitudinal bundle.

Normally the relations between the nuclei of the fifth and tenth cranial nerves are directed and controlled by centers situated higher up. This control is usually not materially interfered with during ether anesthesia, but when chloroform is used the connecting fibers between the two deep origins are given much freer play, and as a consequence, any irritation of the peripheral fibers of the trigeminus may produce, through the cardioinhibitory fibers of the vagus, an amount of disturbance which may vary from only a slight degree of embarrassment to actual cessation of the heart's action. In this way may be explained some of those deplorable accidents which have occurred during adenoid and dental operations, and a safe rule to follow would be never to use chloroform when the area about to be operated on is supplied by sensory fibers of the fifth nerve.

A similar reflex has been proved to occur in operations on the ear, by the experiments of Reik,² who performed a number of operations on the tympanic structures of dogs, and measured and determined accurately the effect produced thereby on the circulatory apparatus. He concludes: "The results of these and similar experiments tend to show that the faintness and other effects which attend operations on the tympanum are due mainly to disturbance of the vasomotor apparatus, through irritation of the sensory nerve supply; that these nerves when stimulated show a depressor effect and usually a cardioinhibitory action, though under some circumstances the pulse-rate may be increased; and that complete anesthesia prevents the transmission of such an influence by these nerves and partial anesthesia weakens this influence."

The occurrence in aural manipulations is of much greater frequency than when the upper respiratory tract is the field of operation. It has been frequently noted and mentioned in the former connection, and has occurred at the hands of all of us. I have seen it on the mere introduction of the speculum, during the incision of a furuncle, during the removal of cerumen, and during operations involving the tympanic membrane and ossicles. The anatomic relations here are of great interest, and afford a ready explanation of the greater frequency with which these symptoms occur in aural compared with rhinolaryngologic work. The nerve supply of the external auditory meatus is derived from the auriculotemporal branch of the trifacial and from the auricular branch of the vagus, while the tympanic membrane depends for its nerve supply on the tympanic plexus, which is made up of the tympanic branch of the glossopharyngeal and the caroticotympanic (least deep petrosal) branch of the carotid plexus of the sympathetic. In the case of afferent impulses originating in the external meatus, the path is evidently one of two, either through the mandibular nerve and gasserian ganglion, as described above, or through the auricular branch of the vagus to the ganglia of the root and trunk, and thence to the small-celled or sensory nucleus common to the ninth, tenth, and the accessory portion of the eleventh. From here to the nucleus ambiguus is but a short and easy step. In the case of the tympanic membrane the path is probably through the tympanic branch of the ninth to the jugular and petrosal ganglia, thence to the sensory nucleus just mentioned, and then to the nucleus ambiguus or motor nucleus common to the ninth and tenth nerves. It is thus evident that the anatomic connection between the external auditory apparatus and the cardioinhibitory apparatus is much closer than that between the upper respiratory tract and the cardioinhibitory center, and in this would seem to lie the explanation of the fact that cardiovascular embarrassment occurs and has been noted so frequently in operations on the former, while in the latter it has passed practically unnoticed.

The after history of the case described is uneventful, with the exception that in spite of the most rigid surgical cleanliness the wound in the soft tissues became infected. As a consequence, there was some annoying edema of the right eyelid, which was, of course, partly due to the necessary division during the operation of the supraorbital artery and vein. This extended to the eyelid of the opposite side, probably on account of pressure on the left angular vein, and for several days both eyes were practically closed. Some ptosis of the right side remained for several weeks, but disappeared as the inflammatory exudate became absorbed. There was, of course, and still is, the usual numbness of the forehead incident to the division of the supraorbital nerve.

The external wound was not allowed to close for 6 weeks, and when the gauze drain was finally removed the wound healed quickly. The accompanying photograph shows what a slight degree of disfigurement remains. A slight pit which will receive the very tip of the little finger and a suggestion of broadening of the nasal end of the eyebrow are all that remain, the rest of the scar being concealed by the eyebrow.

Systematic treatment of the nasal chambers was continued throughout, and for a while an apparently atrophic condition seemed to be developing in the area over which the pus from the infundibulum flowed, but when the pus ceased to form the mucosa speedily returned to its normal condition.

This open method of treating the wound, while necessitating unsightly bandaging or strapping for a considerable time, does certainly seem to be the more rational procedure. What we are after is an ultimate good result, and we should not allow an ultrarefinement of cosmetic treatment as regards the bandaging interfere with our efforts to secure the best final good for our patient. Our final success must depend upon the thoroughness with which cleansing can be carried out, and while there can be no question that it is possible to syringe or douche the sinus from the nose, it is likewise certain that far more thorough irrigation can be carried on through the external wound. And if the operator is careful to see that the sinus, which is allowed to form for therapeutic purposes, is confined to the inner portion of the eyebrow the only deformity which will ensue will be a shallow pit over the dehiscence in the anterior wall and a slight broadening of the eyebrow at the point which was allowed to remain open.

THE OCHSNER TREATMENT OF APPENDICITIS APPLIED AFTER OPERATION.

BY

GEORGE S. BROWN, M.D.,
of Birmingham, Ala.

The fact, that Ochsner's recommendations for the management of the more severe types of appendicitis, have met such general approval or at least favorable comment, indicates plainly that many beside Ochsner have had discouraging results from operation in this class of cases.

Much as has been said and written about the technic of operating and, since Ochsner's paper, as to whether to operate at all, there seems to have been written little or nothing new for several years, as to the treatment of such patients *after* operation. I think I am safe in saying that the most common course pursued after operation is still about what has been followed since the first operations for appendicitis were done. The formula usually followed with a zeal and unswerving faith worthy of a devotional exercise is: (1) Withholding water after ether for a routine number of hours or while the nausea lasts; (2) withholding opium as much as possible because it masks the symptoms and for fear the patient will like it too well; (3) giving purgatives because the surgeon feels better when the patient's bowels move.

As my practice for several years has been exactly opposite of all this it may be of some interest to summarize my cases and results and describe the plan of treatment pursued.

In all I have had 90 cases in the last 7 years of which number 25 were clean cases and 65 were pus cases. I have seen in addition to these about 100 other patients who refused operation or were not operated upon because the cases were so mild as to throw a doubt on the diagnosis in the minds of the attending physicians. Again I have been called to 7 patients who were dying at the time and operation was out of the question. These facts tend to show that we have not been so quick to operate here as in some other communities. Another bit of evidence to the same effect is that the average time at which the operations were done was 7 days after the onset of the symptoms. This average time was greatly due to the fact that 12 of the pus cases were old large abscesses. These were incised and drained and the appendix left. In all the other cases the appendix was removed. The 25 clean cases were not drained and all the patients recovered. Two patients with large abscesses died; one from a subphrenic complication and the other because the abscess had already ruptured into the cavity at the time of operation, and the condition of the patient was too bad to do any more than open and let out the pus. Of the 53 pus cases remaining, in which the appendix was removed, 4 were extraperitoneal and 24 were intraperitoneal abscesses which were unruptured. Only one of these patients died. He had an ugly abscess between the folds of the mesentery, followed by a subphrenic abscess, which also ruptured into the lung and caused his death by pneumonia and sepsis. He did not have peritonitis. He died 5 weeks after the original operation. Of the 25 remaining cases, 3 were cases of ruptured gangrenous appendix and 22 of ruptured intraperitoneal abscesses. One of the patients with a ruptured appendix died from sapremia. The rupture had taken place 18 hours before operation and there had been no inflammatory reaction against the poison. The peritoneum was a dark lead color and the veins were black. The autopsy showed the same condition 2 days later. In the other two, operation was done soon after the appendix became gangrenous and the rupture had just taken place. The contents of the bowel had spilled out and was running through the opening, but the time had been so short that we were able to clean it out and close the abdomen without drainage. Of 22 patients with ruptured intraperitoneal abscesses, 18 had peritonitis in varying degrees of intensity. Twelve of these had diffuse peritonitis in the severe degree that is usually called general peritonitis. Three of these patients died. Two did not rally from the shock of operation. The other patient died after 4 days from regurgitant vomiting, caused, I believe, by a large quantity of castor-oil she had been given before the operation and which we had failed to wash out. The operation was done 10 miles out in the country and the stomach-tube had been forgotten. The reasons for my belief are the following: In spite of the vomiting, 24 hours after the operation her temperature and pulse had fallen from 104° and 140 to 101° and 110, respectively. The autopsy showed that the diffuse peritonitis, which was so marked at the time of the operation, was very much less and that the right iliac region was walled off and draining. Then, too, the vomitus contained oil to the end. These 3 patients who died did not seem to be any worse off at the time of operation than the other 9, a brief history of whose cases follows:

CASE I.—Dr. B., white, aged 53. The patient had had repeated attacks. A sudden attack occurred at 5 a.m., June 29, 1889, accompanied by chill, vomiting, and great pain. Operation was performed at 2 p.m. Temperature was 104° and pulse 130. The appendix was gangrenous; there was diffuse peritonitis; serosa was injected, lymph deposit plentiful, and there were remains of an old abscess cavity around the appendix; the belly was full of seropus and cloudy serum. The bowels contained large quantities of food and gas. The patient was a large fat man and the incision was 8 inches long. The stomach was not washed out. Opium was given, but water was withheld. Regurgitant vomiting persisted for 4 days, then he got

hold of the water pitcher and helped himself to more than a quart. After this was vomited he was much relieved and made a good recovery.

CASE II.—J. L., aged 30, had been very ill for 4 days. A diagnosis was made of gangrenous appendix. Operation was refused until the abscess ruptured and collapse occurred. Operation was done 4 hours later. Diffuse peritonitis was present; the abdomen was full of cloudy serum; pulse 150; temperature 103°; great distention. The patient was given all the water he wanted after the operation and morphin enough to keep him quiet. The tight binder was not used and he suffered a great deal from gas for 5 days, when gas passed per anum. He was then given an enema, his bowels moved, and he recovered rapidly.

CASE III.—W. M., aged 10, had pain all day of November 12, 1902. Next day after a very painful night his temperature went up rapidly to 103° and his pulse to 150. He was given morphin and was removed to the hospital. After the morphin the pulse came down to 114 and the temperature to 101°. Operation was performed 6 hours after symptoms became worse. There was diffuse peritonitis with a gangrenous appendix. Seropus was washed away, lymph of the adhesions wiped away, and the cavity thoroughly drained. He was given opium, lavage was done, the tight binder applied, and all the water he wanted was given to him after the operation. Recovery occurred with hardly any discomfort. There was no distention and bowels moved naturally on the third day.

CASE IV.—P. C., aged 30, suffering from the first attack. The patient had been sick 8 days. The abdomen was swollen and very tender. Pulse 100, temperature 101°. Appendix was gangrenous but walled off. A mild general peritonitis was present in process of spontaneous cure. All adhesions were broken up, lymph wiped away and the cavity flushed and drained. Lavage was done, the tight binder applied, opium and plenty of water were given, and convalescence was very rapid.

CASE V.—A. H., aged 18. First attack. Pulse was 120, temperature 102°, when admitted. Shortly after admission the pain became intense, vomiting ensued and the patient was immediately taken to the operating-room. A large pelvic abscess had ruptured and a diffuse peritonitis was beginning. The appendix was gangrenous and the pelvic cavity was full of cloudy serum. Lymph deposit and adhesions in all the lower abdomen and injection of the serosa over the entire cavity. The appendix was removed, and the cavity wiped, flushed and drained. Lavage was done before leaving the table, the tight binder applied, opium was given and water ad libitum. There was no nausea nor other discomfort. Bowels moved on the fifth day.

CASE VI.—J. M., aged 11, third day of the disease. There was chill, vomiting, and great distention. Pulse was 130, temperature 104°. Gangrenous appendix and diffuse peritonitis. Appendix was removed, adhesions broken up and wiped away and the cavity flushed and drained. Lavage was done before the patient was removed to bed; the tight binder was applied and plenty of opium and water given as needed. Recovery was uneventful.

CASE VII.—E. E. C., aged 22; first attack. The patient was first seen on the fourth day. Pulse 130, temperature 103°. He had two or three hard chills, there was vomiting, great distention, and every symptom of general peritonitis. Operation was performed at once. There was a very great degree of general peritonitis, pus and cloudy serum, and a gangrenous appendix. A collection of pus was also found up under the ribs against the liver just as we were about to close the wound. This was drained. The usual course was pursued but the patient later developed an abscess up under the diaphragm for which 2 secondary operations of resecting the ribs had to be done before he recovered. The peritonitis was controlled at once however by the first operation, followed by opium, the binder, lavage, and water, and no purgatives. This patient seemed worse off at the time of operation than the two who died.

CASE VIII.—J. A., aged 26, white, epileptic. First attack occurred May 4, 1901; 48 hours later operation was done. Diffuse peritonitis was present, and a gangrenous appendix, 8 inches long and nearly as large as the small bowel was found coiled up in the pelvis. Adhesions and plastic exudate were present over the entire lower abdominal cavity. There was a large amount of free seropus in the cavity. The appendix was removed, adhesions were broken up, the cavity wiped, flushed, and drained. Same treatment was followed as in former cases, and convalescence was rapid and comfortable.

CASE IX.—C. W., aged 7, white. The patient was seen September 1, 1902, when he had been very ill for 4 days. Operation was performed at once. Temperature 103°, and pulse 140. There was much distention, a gangrenous appendix, and diffuse peritonitis. In removing the bowels, loop at a time, in order to wipe away the lymph, the bowels prolapsed through coughing, and it was seen that inflammation and its products were present everywhere in the cavity. The peritoneum was wiped clean, and the cavity flushed, and a tight binder applied. The after-treatment consisted of lavage before removing the patient from the table, and the administration of opium and water afterward as in the other cases. Rapid recovery.

CASE X.—M. R., white, aged 17. The patient was seen November 8, 1901, was sick 6 days, and was getting worse all the time; there was great distention, pain, and vomiting. Tem-

perature 104°, pulse 150. A large gangrenous appendix was removed. Diffuse peritonitis was present in extreme degree. Adhesions were broken up, lymph deposit wiped away, and a large quantity of seropus washed out, and the iliac fossa and pelvis drained.

This patient was 20 miles out in the country, and 100 miles away by rail. She did not have very good nursing, but I got a report every day, and according to it she convalesced very rapidly, and for nearly 2 weeks her pulse and temperature were normal. The drains were taken out, and the wound was doing well until about 3 days after the removal of the drains, when she began to have a little fever. I was informed later that she had typhoid fever, but suspecting a secondary abscess, I went to see her, and arrived in time to see her die from the effects of an enormous secondary abscess in the pelvis, death occurring a month after the original operation. This case is recorded as a recovery only as relating to the immediate result of operation for diffuse peritonitis.

In all my clean cases and in nearly all the others, and especially for intraperitoneal abscesses I pursued the course described. Lavage, tight binder, opium, plenty of water to drink and no purgatives until the bowels manifest a disposition to move by the uncomfortable rolling about of the gas and the other symptoms showing that the inflammation is subsiding and the paralysis of the bowel is being overcome.

When the inflammation is active the bowel is paralyzed at that point. For this reason it has always seemed to me very dangerous to give a purgative, the effect of which is to set up an ever increasing activity of the upper part of the bowel which is not inflamed. This peristaltic wave goes to the paralyzed portion and as it can go no further it sets up a return wave which empties the contents of the bowel into the stomach and causes regurgitant vomiting. Emptying the stomach and bowels by irrigation will, as Ochsner has pointed out, favor quiescence of the bowel and the formation of adhesions. Opium also favors quiescence but as it seems to stop the secretions and promote the fermentation of what little food is left after irrigation, thus favoring the formation of gas, it has not been used as much as its other good qualities warrant. By using the binder properly, *i. e.*, keeping it tight as the gas recedes, opium can be used liberally, for its quieting influence on the nervous system and conservation of the patient's strength. The tight binder merely supplements the stiffened up abdominal walls which is nature's feeble way of trying to avert the fearful complication of over-distention. If these muscles are not so supplemented they may, in a short time, become over-distended and then the picture of so-called paralysis of the bowel is complete. Paralysis of the bowel is the only way in which nature can cure a severe case of peritoneal inflammation, therefore it is to be encouraged, but over-distention is dangerous and must be avoided.

For 5 years now I have given my patients all the water they wanted, both before and after ether and I have yet to see anything but good result from the practice. If there is nausea, vomiting cures it in a little while if the patient is given water. If irrigation is sufficiently prolonged it will not only empty the stomach of ether-laden mucus, but will actually wash every particle of ether out of the blood; just as laboratory experiments have shown that morphin, for instance, can be almost totally recovered from the stomach washings, after it has been injected hypodermically. As stated before, opium keeps the bowel quiet and favors adhesions, and when a patient is under its influence his nerve and tissue waste is at a minimum. This effect is so pronounced that for a long time it was regarded as almost a specific for peritonitis and in those days it did cure a great many patients, just as Ochsner is curing them today on the same principle. It cures by aiding nature and nothing cures in any other way. I started out in the regular line of purgatives and was in a constant frenzy to get every patient's bowels to move as soon as possible after an operation and at least 3 of my 7 fatalities in the 90 cases were in some degree due to this effort. I believe that the mortality in such cases as I

have reported would be fearful (and is) if the patients are treated with purgatives. I believe that the mortality of 15% to 48% in cases published some years ago was due to the purgatives that were given. Constipation does not kill and purgatives will not cure general peritonitis, but purgatives are often responsible for a fatal termination. Gas passing on the second, third, or fourth day is a sign that the inflammation is subsiding and that peristalsis is becoming active and at this juncture a purgative will move the bowels and give the patient and the surgeon considerable relief, though the bowels would probably move the next day without a purgative. The bowel movement is the indication of the cure and not the cure itself. The great relief experienced after the movement gives the impression that it is responsible. Hence the cart before the horse.

Finally, if the Ochsner treatment will tide over a patient with a gangrenous appendix, I am convinced that the same method applied *after* the appendix has been removed will give better results, and I have found it so in my practice. Granting that it is best to tide over the worst cases in this way, it is hard to say always just what is a bad enough case in which to institute this treatment. Sometimes we might find ourselves much puzzled when the abdomen is opened and a gangrenous appendix in our hand whether to leave it and close the abdomen and follow out Ochsner's plan, or to take it out and give purgatives. So far as I have been able to read in the current literature there is no other choice, and yet I feel sure we should do neither, but remove it, and then apply the Ochsner treatment. I may add that in all my other abdominal cases I have treated my patients on the same line and have seen nothing but good result from it.

ASTIGMATIC CHANGES.¹

BY

JULIUS POHLMAN, M.D.,
of Buffalo, N. Y.

Such work as published in *American Medicine*, Vol. VI, No. 5, by Drs. Bennett and Clemesha, if carried out according to the views of the authors, will give an excellent idea of astigmatic averages, but not of changes. Even if we had records tabulated for 100,000 cases, they would not convey any knowledge of the changes that take place in the individual and give no proof that the averages of one cycle have changed or will change into the average of the previous or the succeeding cycle. This work was undertaken to determine the changes in the refraction of individual cases. Its study is based upon eyes examined and reexamined by me during a period of 10 years; reexamined from one to ten times at intervals varying from 6 months to 5 years. All eyes below the age of 50 years were examined under a cycloplegic; no doubtful case has been counted, but only those in which a definite change could be measured, and in which the patient reported satisfactory improvements due to the change of glasses. For convenience all parallel axes and all those in which the axes form an angle of 90° or of 180° have been classed as regular, whereas all others, which cannot be classed under these 3 forms, have been called irregular. Hyperopic and myopic corrections have been ignored, because nobody disputes the fact that they change; attention has been given solely to astigmatic errors and their variations.

This paper was written in 3 sections. The first section, embracing 300 cases was ready for presentation at the November meeting of the Club, but its reading was postponed to December, which gave time to write up the second 300 cases; to oblige a colleague, the reading in December was postponed for another month and this allowed the compilation of the full 900 cases, extending

¹ Read before the Buffalo Ophthalmologic Club, January 14, 1901.

over a period of 10 years. This separation into 3 distinct papers brought out a series of unexpected and striking similarities, which would not have been discovered if all the cases had been originally studied for one paper. What was foreshadowed in the first section was emphasized in the second, and strongly corroborated in the final chapter as well as in the totals. Among the first 1,550 patients recorded there were 300 who presented themselves for reexamination; the second 300 were from 1,450 cases and the third 300 needed 1,500 patients to complete the number; practically no difference in the course of 10 years, 1 patient among 5 returned for reexamination. The usual instructions given by the ophthalmologist to the patient, as to the time when a reexamination will be advisable or necessary, make apparently very little impression on that patient, otherwise a distinct increase in the number of reexaminations should be recorded as the years go by; even if we make due allowance for patients leaving the city, or consulting another physician, still these numbers are small enough to prove that patients do not return for reexamination because the physician advises it, but because the reappearance of former bad symptoms forces them again to seek his services. Hundreds, yes, thousands of men and women visit the dentist at regular intervals to keep their teeth in good condition; they don't wait until the tooth aches or shows signs of decay; it would be well for the eyes and the general health of the present and the next generation if the patients of the ophthalmologist would learn to treat their eyes as respectfully as they do their teeth, but the wellknown law of evolution which says that "ornament precedes use" in the development of the human family, finds here again a strange but forceful confirmation, the teeth are seen, the refractive error of the eye is only felt.

The proportion between male and female patients among the 4,500 cases studied was 62 females to 38 males; i. e., about 3 women to 2 men. Among the 900 reexamined cases were 573 females and 327 males, 64 to 36, practically the same proportion. Taking the 3 sections separately, the first 300 gave 190 females to 110 males, 63 to 37; the second 300 gave 197 females to 103 males, 65 to 35; the third 300 gave 186 females to 114 males, 62 to 38.

Among the reexamined 900 cases were 682 hyperopes and 218 myopes, 76% of the former to 24% of the latter. Divided again into the 3 sections, the first 300 gave 230 hyperopes to 70 myopes, 77% and 23%; the second 300 gave 231 hyperopes to 69 myopes, 77% and 23%; the third 300 gave 221 hyperopes to 79 myopes, 74% and 26%.

Among the 284 of the reexamined 900, 32% showed changes in their astigmatic corrections, 1 case in every 3½. These 284 cases presented 171 females and 113 males; i. e., 60% to 40%. There were among them 205 hyperopes and 79 myopes, 72% of the former and 28% of the latter.

It seems from these percentages that female and male, hyperope and myope, average about the same, whether for the total numbers or for the reexamined or the changed eyes, and as far as the return for reexamination is concerned, the difference between 62 females and 38 males among the 4,500 cases, and 64 females to 36 males in the 900 reexamined cases, shows that sex has no influence whatever and that the woman hates to part with her money for the payment of doctor bills as much as the man, and that one sex is just as loath to learn as the other that the appreciation of the "useful" necessitates a higher point of view than that of the "ornamental."

Among the 900 reexamined cases, classified according to age, we find:

Below 10 years	59
Between 10 and 20 years	166
Between 20 and 30 years	276
Between 30 and 40 years	182
Forty years and over	217

In the 284 changed cases, the age is as follows:

Below 10 years	22
Between 10 and 20 years	45
Between 20 and 30 years	100
Between 30 and 40 years	57
Forty years and over	60

Or to equalize these figures to a common base:

Up to 10 years, 37 among 100 had changed; from 10 to 20 years, 28 among 100 had changed; from 20 to 30 years, 36 among 100 had changed; from 30 to 40 years, 31 among 100 had changed; from 40 years up, 28 among 100 had changed.

Small differences indeed, and considering that the total change was 32%, these averages appear good enough to warrant the statement that, in spite of preconceived ideas, the different ages change with about equal frequency. Sex, age, hyperopia, and myopia, according to the foregoing figures, will have to be excluded as factors in the production of astigmatic changes.

The 284 cases found in which changes had taken place are classified as follows:

1. Increase of astigmatism, 142 cases, 50%.
2. Change of astigmatic axis, 89 cases, 31%.
3. Increase of astigmatism and change of axis, 21 cases, 7%.
4. Change of regular to irregular axis, 16 cases, 6%.
5. Change of irregular to regular axis, 16 cases, 6%.

To recapitulate: From a study of 900 cases examined and reexamined, nearly every third showed changes in the astigmatism; 50%, half of all the changes found, presented a simple increase in the quantity of astigmatism without any change of axis; 31% gave merely a change of axis; these two combined accounted for 81% of all the changes recorded. The other 19% were almost equally divided between (1) increase of astigmatism plus change of axis; (2) change of regular to irregular; and (3) change of irregular to regular axis.

It will be exceedingly interesting to know whether different series from the records of other observers present similarities like the foregoing. It would be more interesting if such records gave an equally large and rapid amount of changes in the astigmatism of the eyes studied, and if they do, the accumulated evidence will teach us tolerance with the work of our fellow ophthalmologists, and diminish the spirit of infallibility which so often comes to the surface in the most unexpected places.

SPECIAL ARTICLES

THE SOCIETY FOR EXPERIMENTAL BIOLOGY AND MEDICINE.

Proceedings Reported by the Secretary,
WILLIAM J. GIES, M.S., PH.D.,
of New York.

The fifth regular meeting of the Society for Experimental Biology and Medicine was held on the evening of February 17, in the rooms of the department of pathology of the Cornell University Medical College. Dr. S. J. Meltzer presided.

MEMBERS PRESENT.—Adler, Calkins, Crampton, Dunham, Ewing, Gies, Jackson, Levene, Lusk, Meltzer, Murlin, Norris, Richards, Wadsworth, Wallace, Wilson, Woodworth, Yatsu.

ABSTRACTS¹ OF THE REPORTS ON ORIGINAL RESEARCHES.

"The nature and basis of sexual selection in moths:" H. E. CRAMPTON.

The object of the investigation described was to obtain a quantitative expression for the strength of the mating instinct in certain species of large saturniid moths (*Philosamia cynthia* and *Samia cecropia*), and to determine the correlation between the mating instinct and structural characters. The results of earlier statistical studies upon the pupas of these species were reviewed, dealing with the nature and basis of the process of natural selection during the period before emergence and at emergence. It was shown that:

1. Those pupas which die after pupation and prior to metamorphosis are structurally different from and more variable than those individuals which successfully survive the pupal period.

¹The authors of the reports have furnished the abstracts. The secretary has made only a few abbreviations and minor alterations in them.

2. Those pupas which become perfect moths are likewise different from those which cannot emerge as perfect moths.

3. The basis for selective elimination is to be sought in correlation between the various structures.

The mating period follows immediately after metamorphosis, when certain individuals with weak mating instinct fail to take part in the production of the next generation, and are thus "sexually eliminated." In order to determine the points mentioned above, pupas of the 2 species named were isolated as the time for metamorphosis approached, and upon emergence were given one opportunity to mate. It was therefore possible to compare the pupas of the 2 classes of mating and nonmating individuals. The results, briefly stated, are:

1. That even slightly imperfect moths possess very little mating instinct, or in other words, that with the structural conditions associated with an imperfect power of emergence, is correlated a low grade of mating ability.

2. That the mating individuals of the perfect class differ structurally to a certain extent from the nonmating ones, but they are very much less variable than the latter class.

The importance of these results from the standpoint of inheritance and evolution is sufficiently clear to render extended discussion unnecessary.

"Observations on a serous fluid of unusually high molecular concentration:" E. K. DUNHAM.

The fluid was removed from the pleural cavity of a man suffering from lobar pneumonia. The patient was a scene-shifter in a theater, and had suffered considerable pain in the chest for 4 months before his admission to the hospital. His occupation required severe labor for brief periods, during which he became much heated, with intervals of leisure and exposure to cold drafts of air. The immediate reasons for his admission were a chill and inability to continue work. There was nothing unusual in the clinical course of the pneumonia or peculiar in his treatment. A few days after he entered the hospital 400 cc. of a clear serous fluid was aspirated from the affected side of the chest, and was examined on the same day, with the following results:

Distinctly alkaline; specific gravity, 1.021; depression of freezing point, 1.383° C. (mean of 3 examinations with different portions of the fluid, 1.395° C., 1.385° C., and 1.370° C., respectively); electric conductivity, 0.009119; chlorin calculated as NaCl, 0.58%; total nitrogen, 0.84%; nitrogen from washed tannic acid precipitate expressed in percentage of the fluid, 0.83%; proteid (N×6.25), 5.21% of the fluid; traces of reducing substance (sugar?) after removing proteids with ferric acetate; traces of nitrogen liberated by hypobromite of soda; no extractives of appreciable amount upon shaking with ether, acetic ether, or chloroform.

The matter of chief interest in the results was the considerable depression of the freezing point—0.81° C. greater than that by the blood, which was found to be 0.57° C. This 0.81° C. represents nearly 0.438 gram molecule in solution in excess of the molecular concentration of the blood, and appears to be a clear indication that osmotic interchanges between this fluid and the blood did not freely take place, possibly because of a thick layer of fibrin upon the pleural surfaces. Such a deposit would not, however, explain the high molecular concentration of the fluid. It appears most probable that this was produced subsequent to the formation of the fluid, by cleavages in the larger molecules originally present in solution, or by the solution of substances not at first dissolved. These substances could not be dissociable, because the electric conductivity was rather lower than is usual in such fluids. If the substances causing the high molecular concentration were organic compounds, they were not extractives, soluble in ether, acetic ether, or chloroform.

On the assumption that cleavage products of proteid substances, precipitable with tannic acid, might be present and cause the unusual depression of the freezing-point, the following experiments were made: Sterile horse serum, which had not been subjected to heat, was divided into portions. Of these some were kept for controls and others were inoculated with pure cultures of *Staphylococcus pyogenes aureus* or Fraenkel's pneumococcus. Freezing-point determinations were made on certain of these portions and the rest were sealed up in pipets

holding 100 cc. each. These were incubated at 37° C. for a week, when freezing-point determinations were made on one of the controls and one of the tubes inoculated with each of the bacteria mentioned. Cultures at this time showed the presence of great numbers of the species used, with no admixture of other species. The remaining tubes were left in the incubator for several months, when cultures proved to be sterile. The results of physicochemic examination of these serums are tabulated below:

HORSE SERUM A.			
Sterile Controls.		Inoculated with <i>Staphylococcus</i> .	
	°C		°C
1903			
May 19	△=0.580; K=0.009394	△=0.585; K=0.009370	
May 26	△=0.580; K=0.009491	△=0.585; K=0.009674	
1904			
Jan. 16	△=0.590; K=0.009684	△=0.640; K=0.010128	
HORSE SERUM B.			
Sterile Controls.		Inoculated with <i>Staphylococcus</i> .	
	°C		°C
1903			
May 21	△=0.560; K=0.009516	— — — —	
May 28	△=0.560; K=0.009516	△=0.580	— — — —
1904			
Jan. 15	△=0.600; K=0.009897	△=0.640; K=0.010372	

These data show but slight changes in the molecular concentration of the serums, and such changes as have occurred occasion an increase in the electric conductivity as well as in the depression of the freezing-point, showing that dissociable bodies have been produced. The experiments, therefore, fail to explain the high molecular concentration of the serous fluid from the chest, but it is possible that further experimentation in this direction will be more successful.

"An experimental study of the eosinophile cells during infection with an animal parasite—*Trichina spiralis*:" EUGENE L. OPIE. [Presented by James Ewing.]

The administration of *Trichina spiralis* to the guinea pig causes an increase of the eosinophile leukocytes in the blood, comparable to that which accompanies human infection. There is no constant alteration of the number of these cells until the end of the second week after infection, when the relative and absolute number rapidly increases and reaches a maximum at the end of the third week. At this time embryonic trichinas are in process of transmission from the intestinal mucosa by way of the lymphatic vessels and the blood through the lungs to the vascular system.

Eosinophile cells accumulate in the mesenteric lymph-glands and in the lungs, and form foci, which resemble small abscesses, in which polynuclear leukocytes are replaced by eosinophile cells. These cells are provided with polymorphous nuclei and do not differ from the eosinophile leukocytes of the circulating blood. Accumulation of the eosinophile cells in the mesenteric lymph-glands and in the lungs is explained by the transmission of the embryonic parasites through these organs.

Increase of eosinophile cells in the blood and in other organs is accompanied by characteristic changes in the bone marrow. The fat is diminished in amount and cellular elements replace it. Cells with eosinophile granulation are present in immense number and particularly numerous are the eosinophile myelocytes, cells peculiar to the bone marrow. Eosinophile cells undergoing mitotic division are more numerous than usual.

The number of eosinophile leukocytes in the blood always diminishes before death, so that the proportion is usually less than 1%. Infection with a very large number of trichinas causes a rapid diminution of the number of eosinophile leukocytes, and is quickly fatal. The eosinophile cells of the bone marrow exhibit degenerative changes, of which nuclear fragmentation is most characteristic. Similar changes may affect the eosinophile cells of the intestinal mucosa and of the mesenteric lymph-glands. Mild infection stimulates the eosinophile cells to multiplication, but severe infection causes their destruction.

"Subcortical expressive reflexes and their spinal pathways:" R. S. WOODWORTH.

Dr. Woodworth reported on some experiments done in collaboration with Professor Sherrington in the latter's laboratory. It was shown that in a recently decerebrated cat, powerful

sensory stimuli evoked reactions such as in a normal animal would be expressive of pain, anger, and other similar emotions. Such reactions are therefore primarily subcortical reflexes and not dependent on the organ of consciousness. The "ether cry" also appeared in decerebrate animals. The sensory spinal pathway, by which these signs of pain were aroused, was found by experiments in which partial cross-sections of the cord were made, to run not in the posterior, but in the lateral columns. The pain pathway from either side of the body runs up both halves of the cord, but more largely up the opposite half.

"An experimental study of the cause of shock:" W. H. HOWELL. [Presented by S. J. Meltzer.]

Professor Howell's experiments were made upon dogs anesthetized with morphia and ether, and brought into a condition of shock by operations of various kinds. Blood-pressure records were obtained in the usual way during the experiment. The following general conclusions were reached:

1. The most important and dangerous feature of severe shock is a long-continued, practically permanent fall in blood-pressure to about 20 mm. to 40 mm. of Hg. This condition is designated as vascular shock and is due to a long-lasting loss of activity of the vasoconstrictor center.

2. A second important result of shock is a very rapid and feeble heart-beat. This condition is designated as cardiac shock; since, although it may result secondarily from the permanent fall in blood-pressure, it may also occur quite independently of the vascular shock as a primary result of the operations. Cardiac shock, so far at least as the rate of beat is concerned, is due to a more or less permanent loss of activity of the cardioinhibitory center.

3. Intravenous infusions of alkaline salt solutions (NaCl, 0.6%—Na₂CO₃, 0.5%) cause a rise of pressure by increasing the force of the heart-beat. The effect is more durable than with salt solution alone and may be renewed by repeating the injection.

4. The fundamental cause of vascular and cardiac shock is not exhaustion of the vasomotor and cardioinhibitory centers from over-activity, but a more or less permanent inhibition of these centers from excessive stimulation of the inhibitory paths.

NEW MEMBERS.—Drs. Isaac Levin and J. P. Atkinson were elected to membership.

OFFICERS.—Officers for the ensuing term were elected as follows: President, S. J. Meltzer; Vice-President, James Ewing; Secretary, William J. Gies; Librarian, Graham Lusk; Treasurer, Gary N. Calkins.

Three Hundred Men in Chicago Fined for Spitting.—The police have at last found an ordinance they can enforce. It is the antisputting ordinance. More than 300 men have been fined in 2 days for spitting in public places. All women's clubs are backing the crusade.

Decrease of Tuberculosis throughout the United States.—In the *Maryland Medical Journal* for February, Mr. Frederick Hoffman says: The mortality from tuberculosis in the United States decreased from 25 per 10,000 in 1890 to 19 in 1900, a decline of 24%. In cities the rate in 1900 was 20, against 13 for the rural districts. For males the rate was 19, against 16 for females. In cities the rate for males was 21; for females, 16. But in the country districts the deathrate was for males, 12, against 14 for females. The deathrate from tuberculosis for the white population in 1900 was 17 per 10,000, against 49 for the colored population—a remarkable disproportion. In cities the colored deathrate from tuberculosis was even higher, being 50, against 19 for the white element; in the rural districts the rate for colored people was 32, against 13 for the whites. For both races, however, there was a decrease of the mortality in the decade 1890-1900, the decrease being attributed to "an improved environment." Americans of native stock have a lower rate, it is found, than foreigners, or persons of foreign extraction, their rate being 13, against 17 for the aggregate white population. In comparison with Baltimore's rate of mortality from tuberculosis of about 22 per 10,000 in 1901, other cities make the following exhibit: San Francisco, 29; Orange, N. J., 27; New York, 26; Newark, N. J., 26; Pueblo, Col., 26; Jersey City, N. J., 25; Boston, 24; Brooklyn, 22; Cambridge, Mass., 22; Paterson, N. J., 22; Providence, R. I., 22; Holyoke, Mass., 21; Worcester, Mass., 21; Cincinnati, 21; Philadelphia, 21; Lowell, Mass., 21; Manchester, N. H., 17; Binghamton, N. Y., 17; New Bedford, Mass., 16; Fall River, 16; Chicago, 15; Lynn, Mass., 14; Gloucester, 14; St. Paul, 14; Milwaukee, 13; Minneapolis, 12; Spokane, 12.

THE WORLD'S LATEST LITERATURE

Journal of the American Medical Association.

March 12, 1904. [Vol. XLII, No. 11.]

1. Perforating Gastric Ulcer; Posterior Gastroenterostomy; Fowler's Position. J. H. MUSSER and W. W. KEEN.
2. Bovine and Human Tuberculosis. D. E. SALMON.
3. The Condition of the Blood in Patients Suffering from Pulmonary Tuberculosis. JOHN M. SWAN.
4. The Present Conception of the Perirenal Fascia and Its Role in Fixation of the Kidney. D. D. LEWIS.
5. The Value of an Injury. L. SEXTON.

1.—Perforating Gastric Ulcer.—J. H. Musser and W. W. Keen report a case in which extreme hyperchlorhydria doubtless contributed to the perforation. The importance of neutralizing the acid when food which takes it up is not permitted should be emphasized. Early operation when the stomach was empty doubtless saved the patient's life. There was no spasm of the abdominal walls on account of muscular atrophy. The perforation was 5 mm. ($\frac{1}{4}$ in.) in diameter, and in the middle of the pylorus anteriorly. The transverse colon was turned up, a hole torn through the mesocolon and a posterior gastroenterostomy done with a Murphy button, the patient being placed in bed in Fowler's position. The recovery from so serious a lesion and operation in a woman past 70 is sufficient reason for recording the case. [H.M.]

2.—Bovine and Human Tuberculosis.—D. E. Salmon sums up the results of other observers, who found tubercle bacilli in human lesions, which had about the same virulence for cattle and other animals as bacilli from bovine animals. Since bovine cultures have sometimes failed to produce generalized tuberculosis in cattle and some human cultures have produced it, shall we conclude that such nonvirulent cultures are in reality of human origin, the original animal being infected by man? Inoculation in cattle to decide the source of a bacillus seems an uncertain method of diagnosis. Four cases of human tuberculosis virulent for cattle were found among 16 children; therefore, according to Koch's method of classification, 25% of tested cases among children are of bovine origin. Two cultures from children were found identical in morphology with the bovine bacillus. Human bacilli with bovine peculiarities have had their morphology changed by being passed through cats, but in consequence increased in virulence. This and similar experiments indicate that types are inconstant in morphology and virulence. When Koch estimated the danger of infection from cattle as hardly greater than that of hereditary transmission and advised taking no measures against it he did immense harm, which sanitarians must endeavor to correct. The location of a primary focus is of little value in determining the origin of infection. Bacilli may pass through the walls of the intestine without producing a lesion at the point of entrance. It is impossible to prove that a given individual has not been exposed to infection by bacilli of either human or bovine tuberculosis. [H.M.]

3.—The Blood in Pulmonary Tuberculosis.—J. M. Swan finds the blood picture not constant. The average case in the first stage shows the erythrocytes slightly reduced, moderate reduction of hemoglobin, and a normal leukocyte count. The second stage presents varying degrees of leukocytosis, due to an increase in polymorphonuclear neutrophile cells. Erythrocytes are about normal and hemoglobin often so. Hemorrhage is usually followed by marked reduction in hemoglobin and slight reduction in erythrocytes. Leukocytosis is not invariable. Albuminuria appears to cause no constant change in the blood picture. In tuberculous diarrhea erythrocytes and hemoglobin percentage are reduced with increase of leukocytes. Pleurisy is usually accompanied by polymorphonuclear neutrophile leukocytosis. Extensive cavity formation from tuberculous degeneration and other causes cannot be differentiated. Leukocytosis is not a constant feature. Absence of eosinophile cells is an unfavorable prognostic sign. Increase indicates a tendency to arrest in the progress of the disease. [H.M.]

4.—The Perirenal Fascia.—D. D. Lewis records various descriptions of the fascia all differing somewhat as to the attachments and making no mention of a constant anterior layer. As the subperitoneal fascia approaches the lateral margins of the kidneys it divides into a prerenal and retrerenal

layer. In the embryo the anterior surface is covered by parietal peritoneum. Anatomists differ as to the time the fatty capsule develops. The writer describes the coverings and their relations in detail with cuts of vertical and horizontal sections in illustration. The fascia is the most important factor in maintaining normal position though the neighboring organs are important accessories. Harris and Andrews were the first to realize the full surgical significance of the fascia. The good results from Senn's gauze packing are dependent on broad bands of adhesion between the lower pole of the kidney and the retrorenal fascia. If this were sutured into the fibrous capsule, lasting results should be obtained. This direct suture could be easily combined with Senn's method. [H.M.]

5.—The Value of an Injury.—L. Sexton says when we remember how difficult it is to fix any sort of an estimate on physical suffering or mental distress by the standard of a dollar, we realize the difficulty of discussing the subject in hand. The injury generally fixes the price, and unless the verdict is so excessive or grossly inadequate as to indicate passion, prejudice or corruption, it is generally allowed to stand. The writer cites a number of cases showing the widely varying estimates made by juries. For injuries resulting in death, verdicts show the greatest possible variation. A jury has more sympathy for a permanent cripple than for the heirs of a dead man, unless these happen to be a pretty widow and orphaned children. [H.M.]

Boston Medical and Surgical Journal.

1. The General Management of Diabetes. FREDERICK C. SHATTUCK.
2. Medical Treatment of Diabetes. W. H. THOMSON.
3. A Comparison between the Medical Uses of the Röntgen Rays and the Rays from the Salts of Radium. FRANCIS H. WILLIAMS.
4. The Prognosis of Idiopathic Pleurisy. GEORGE G. SEARS.

1.—General Management of Diabetes.—F. C. Shattuck includes all grades of failure to oxidize sugar under the term diabetes. Drugs are of subordinate value to diet and mode of life. It is best to enforce absolute or nearly absolute diet at first, unless the case is very mild or very severe. Quantity is only next in importance to quality. Body-weight should be ascertained weekly. The patient should be given a rough idea of the size of a given weight of bread, meat, and fat. Increase in fats may be as important as diminution of starch. In favorable cases the sugar disappears in 2 or 3 weeks. The period of strict dieting depends on the type of the disease. No diabetic bread which is palatable for any length of time is safe. If alcohol is desirable whisky, brandy, or a dry wine should be given. A day of starvation once every 2 or 3 months is useful. Beef tea may be given without invalidating the fast. Careful attention should be given to the bowels. Hot or vapor baths followed by friction are useful if the skin is dry. Cold baths may be used if reaction is prompt. Diabetics are sensitive to cold and should wear silk or wool underwear, and have several overcoats varying in warmth. Working hours should be shortened. Sunshine and open fires are important in the treatment. Muscular exercise burns up the sugar, and is better taken out doors. Before 20 the disease is sure to be severe, but life may be prolonged even 10 years under rigid diet, etc. [H.M.]

2.—Medical Treatment of Diabetes.—W. H. Thomson thinks the only valid distinction between glycosuria and diabetes is the presence of diacetic acid in the urine. His practice is to pronounce a glycosuria of over a year, diabetes. Excessive excretion of urea and obesity call for special medication, even when the sugar has disappeared. Opium derivatives are only functional remedies, and in therapeutic doses do not affect structure or nutrition. Alcohol produces organic changes only by virtue of its chemic and not by its nervine properties. Opium may diminish the sugar in the urine, but has no effect on the disease causing that symptom. The writer advocates free use of cod-liver oil, with pepsin and bismuth. The younger the patient the more persistently he urges it. It diminishes both sugar and urea when well borne by the stomach. Obesity and sedentary habits contraindicate it, but it is useful with many elderly people. He believes diabetes is largely a muscle disease, and to increase muscular power

through increase of oxygen he gives all the iron the patient can take, guarding against constipation. He has succeeded better in controlling the disease by antiseptics than any other drugs, except the above, including arsenic in this class. When speedy reduction of sugar is imperative, he gives 15 gr. each of antipyrin and sodium benzoate 4 times daily, after a time substituting 15 gr. of aspirin, with 10 gr. of bismuth salicylate. Salines should not be given to any one who is losing flesh. In coma he advises prolonged intestinal irrigation with hot normal saline solution, using Kemp's rectal irrigator. Hypodermics of 7 gr. to 14 gr. of camphor in sterilized almond oil or olive oil best sustain the failing heart, while diluted milk with all the sodium bicarbonate the patient can take is the only recourse for food. [H.M.]

3.—Comparison between the Medical Use of Röntgen Rays and Radium Rays.—Francis H. Williams compares the medical use of these 2 agents in the several ways in which they are used in medicine and surgery, and concludes as follows: 1. The rays from radium salts, unlike the röntgen rays, are not serviceable in diagnosis either by means of radiographs or of fluoroscopic examinations. 2. The beta rays are useful as a therapeutic agent in certain skin diseases and newgrowths, if the diseased tissues are superficial or are not more than about 1.25 cm. ($\frac{1}{2}$ in.) below the surface of the skin or accessible mucous membranes. 3. The beta rays from radium salts will heal some cases of newgrowths that are not healed by the röntgen rays, and they act more promptly, but not over so large a surface at one time as the röntgen rays. 4. Radium salts of an activity of 8,000, or considerably more, are not sufficiently strong to be efficient. Pure radium salts, which have a radioactivity of about 1,500,000, are not too strong for the work to be done. 5. The radiation from radium salts, unlike that from the röntgen ray tube, is uniform. 6. Great care should be exercised to avoid burns. [A.B.C.]

4.—Prognosis of Idiopathic Pleurisy.—G. G. Sears is not able, after a study of his figures, to hold so hopeful a view as Cabot, then giving reason for the suspicion that an attack of pleurisy is a manifestation of a constitutional taint which may be the cause of death years after apparent recovery. How great the danger is, the figures do not show, for the only conclusions they justify are these: About 10% of the cases are known to have developed tuberculosis. Over 55% of all cases which were followed to their death, died from tuberculosis. Tuberculosis, when it occurred, developed within 5 years in over 50%, and within 10 years in over 70%. This danger is much increased by a tuberculous family history or a personal history of some form of tuberculosis previous to the attack. [H.M.]

7. Remarks on the Preparation of Vaccine Virus. JOHN F. ANDERSON.

1.—Secondary Laparotomy.—H. C. Coe says that the principal indication for a second operation is pain, either the same of which the patient previously complained, or a new form more severe than before. Dysmenorrhea, menorrhagia, vesical irritation, gastrointestinal disturbance—each of these symptoms may be so severe as to require surgical relief; but pain is the one which usually makes the patient willing to submit to a second section. In his experience intestinal adhesions have been the most common cause of distressing symptoms, varying in severity from obstinate gastric irritation to intestinal obstruction. Hemorrhages, so profuse as actually to sap the vitality of the patient, not infrequently call for the removal of the uterus, even when the latter is small and atrophied, and the curet shows no evidence of disease of the endometrium. Dysmenorrhea may be marked in connection with cystic or cirrhotic changes following resection of the ovary. Coe is

strongly averse to resection of ovaries and tubes in pus cases, though he has left ovaries or parts of ovaries (never the tubes), with gratifying results. The only way to treat a pus-tube is to excise it entirely, and to suture the uterine wound and broad ligament with continuous catgut. In order to draw a correct inference as to the probable morbid condition, one should know the exact nature of the former operation, and have a complete history of the patient subsequently. Unfortunately, this is seldom possible in hospital practice, even in case of one's own patients. [W.K.]

2.—See *American Medicine*, Vol. V, No. 21, p. 822.

3.—**Strangulated Hernia.**—John F. Erdmann reports a total of 58 cases of inguinal, femoral, umbilical, and ventral hernias, all operated upon by him for strangulation during the past 8 years; of these, 31 were inguinal, all occurring in males. This is unusual, since in Coley's series of 937 cases of inguinal hernia, 181 occurred in females. Among the 31 above cases there were 5 deaths; 19 of the 58 cases were femoral in character, of which 4 were in males and 15 in females; 2 died. One case occurring in a male was reduced *en bloc* or *en masse*; laparotomy was performed 48 hours later, the true condition found, but the patient died. There were 6 cases of umbilical hernia, among which there was 1 death; there were 2 cases of ventral hernia with 1 death. Of the entire series there were 17 cases of excision, from 3 inches to 10 inches excised in all cases. The youngest excision case occurred in a male 5 years old, death occurring from general septic peritonitis. The youngest patient was a male 13 days old; left inguinal hernia; no anesthetic; recovery. The oldest was a female, 86; femoral hernia; local anesthesia; recovery. The author insists that so-called incarcerated hernia, since it is in reality the first stage of a strangulated hernia, should be omitted from the textbooks and should be classed as strangulated hernia, or at least, as demanding immediate surgical interference. [A.B.C.]

5.—**The Relation of Physical Defects to Mental Development.**—George Stockton says that to determine the frequency of the association of physical stigmas of degeneracy with abnormal mental states, he examined 1,000 cases in the Columbus State Hospital, and recorded the measurements of the head, calculated the cephalic index, and noted abnormalities and asymmetries of the cranium, face, palate, and ears. He noted evidences of defective development of the body and extremities. Out of this number, 50 white male patients were selected indiscriminately to form a series on which to base conclusions. From these the author gives a series of figures with reference to the cephalic index, the cranium, the face, eyes, nose, lower jaw, palate, ear, etc., which, while too extended to embrace in an abstract, are of much interest. He says: "Counting wellmarked cranial peculiarities, stigmas of the ear, facial asymmetry, defects in the palate, the eye muscles, the body and extremities, each under a single head, our notes show that 2 stigmas were found in 7 cases, 3 in 9 cases, 4 in 17 cases, 5 in 8 cases, 6 in 6 cases, and 7 in 3 cases." He further states that in the face of facts such as these, and the prominence given to mental and physical stigmas by eminent authors, it seems they are entitled to greater consideration and more careful study. [A.B.C.]

6.—**Mastoiditis.**—E. H. Pomeroy states that this affection is probably always caused by bacterial infection. The most prominent symptom of mastoiditis, and the one which can be called almost pathognomonic is a falling forward and downward, or a protrusion, of the external ear. Taking a case of a patient at any age, showing a drooping or protruding ear, with or without slight increase of redness of the surface back of the ear, with a history of a preceding otitis media, with or without discharge of pus through the external auricular canal, and the case will almost certainly be one of mastoiditis. He emphasizes the point that every case of severe disease of infancy should be carefully examined as to the condition of the middle ear, for Ponfick has demonstrated that in 100 autopsies of unselected cases of infants dying under the age of 2 years, there was scarcely one without pus in the middle ear. Prophylactic treatment of the middle ear will, in the overwhelming cases, give relief. Treatment further than this is distinctly surgical. This procedure is very simple. A good free incision should be made $\frac{1}{2}$ in. posterior to the edge of the external auditory

meatus, 1 in. or more in length. Then the periosteum is lifted from about the incision, especially forward, and the gouge is used carefully from above downward, or the burr with the dental engine, all bleeding points being controlled before the bone is opened into. The internal administration of calcium sulfid, in doses of $\frac{1}{10}$ gr. to $\frac{1}{2}$ gr., 3 or 4 times daily, to patients suffering from mastoiditis, will often prove of distinct value, but should not be relied upon to the exclusion of surgical treatment. [A.B.C.]

7.—**Preparation of Vaccine Virus.**—J. F. Anderson agrees with Rosenau that too much dependence is placed by manufacturers on the germicidal action of glycerin, which is feeble. It probably acts by abstracting water from the germ, its power being much greater at the temperature of the body than in the ice-chest. Pus cocci are killed by it in the incubator in 2 weeks, but live for months in the ice-chest. Colon bacteria are markedly resistant to its action, and it has practically no effect on spores. In the inspections of establishments conducted by the national government some were found in excellent condition, others not. In some plants the close proximity of horses made tetanus contamination possible. The floors were of wood soaked with discharges, and not properly sloped and guttered. The windows were not screened. When the pulp was to be taken, the site was flooded with ordinary tap water, the pulp scraped off and put in an unsterilized container. The methods of sterilization of points, tubes, and other containers were often crude. Examination showed a high degree of bacterial contamination, some of the organisms being virulent for laboratory animals. Tetanus was never found. Recently sodium biborate, boric acid, carbolic acid, chloroform, and potassium cyanid have been found valuable. Chloroform frees the pulp from nonsporebearing germs in a few hours to 7 days, one-quarter the time required by glycerin. Potassium cyanid exerts complete bactericidal action and then volatilizes in 5 or 6 days. [H.M.]

New York Medical Journal.

5. Preliminary Report of Bilateral Excision of the Superior and Middle Cervical Sympathetic Ganglia in 5 Cases of Epilepsy. S. D. HOPKINS.
6. Tertiary Syphilis of the Nose and Pharynx. (Continued). W. SCOTT RENNER.

2.—**Postdiphtheric Paralysis of Accommodation.**—Aaron Brav says this condition occurs in about 10% of cases of diphtheria. As a rule, it sets in during the stage of convalescence, from 3 to 4 weeks after all symptoms characteristic of the disease have subsided. This form of paralysis is more common than the other forms of ocular palsies, and is next in frequency to paralysis of the pharyngeal vault and soft palate. It is never a complete paralysis and is always bilateral, affecting both eyes simultaneously. The degree of the paralysis is by no means an index of the virulence and intensity of the disease causing it. Paresis of accommodation as a sequel to an inflammatory condition of the pharynx is always of specific origin, and is caused by the poison produced by the Klebs-Löffler bacillus. Brav says there seems to be a general tendency to the belief that it is a peripheral neuritis, as there is a great susceptibility of the nervous system to the diphtheric toxin. He adds that it may be due to a local disturbance of the circulation and that nerve force is restored as soon as the circulation readjusts itself. Paralysis of accommodation is due to paralysis of part of the oculomotor nerve innervating the ciliary muscles, and may either exist alone, or be a symptom of a complete paralysis of the third nerve. Proper care during the period of convalescence would most probably lessen the frequency of postdiphtheric palsies. Glasses should not be prescribed, except in high degrees of hyperopia. Fresh air, good food, absolute rest, physical and mental, and a tonic of iron, quinin, and strychnin are all that is required. [C.A.O.]

3.—**Jugular Thrombosis in Pulmonary Tuberculosis.**

—C. J. Aldrich gives a short review of 9 cases of thrombosis of the jugular veins in pulmonary tuberculosis, that have been collected from the literature, and reports another case in full that occurred in his practice. His case is that of a woman of 27, who, while in the last stages of chronic pulmonary tuberculosis, developed a left internal jugular thrombosis, which extended through the subclavian down the axillary into the basilic veins. Two weeks later a like thrombosis appeared on the right side and extended to the veins of the arm. Death occurred from cerebral sinus thrombosis from extension of the thrombus in the right internal jugular vein. The author says it is remarkable that the condition is not more commonly observed as a complication of pulmonary tuberculosis. In the late stages of pulmonary tuberculosis we have very grave changes in the blood. It is lacking in the normal nutritive constituents; it contains some bacteria and the toxins of many more, and when the disease has overwhelmed the normal resistance of the body, it teems with the more or less virulent microorganisms of a mixed infection. Alterations of the venous wall late in pulmonary tuberculosis are to be expected. The poverty of the blood, the continued elevation of the temperature, must result in a lowered nutrition and a consequent diminution of its normal power of resistance. The presence of foreign matter in the blood-stream tends to the development of fibrin ferments which, as in all septic conditions, favor coagulation. Lastly, when the forces of life are expended, the degenerated heart-muscle cannot force the blood-stream on; stasis develops, microorganisms attach themselves to the venous walls, phlebitis occurs, thrombi form, and death comes. [C.A.O.]

5.—Excision of Ganglions in Epilepsy.—S. D. Hopkins gives a preliminary report of bilateral excision of the superior and middle cervical sympathetic ganglions in 5 cases of epilepsy. One patient has been free from epilepsy for a period of 2 years and 1 month. The 4 remaining patients, except Case II, have had the bromid and antipyrin treatment for years without any beneficial effect. In all the cases the severity and number of attacks were lessened. [C.A.O.]

1.—Intestinal Infection by *Bacillus Dysenteriae*.—La Fetra and Howland, after an analysis of his cases, note the following points: 1. The great prevalence of the dysentery organism in diarrhea in the summer months, 62 out of 64 cases reacting positively, these being ambulant patients seen very early. 2. All clinical types of diarrheal disease are to be found among these cases, including the mildest forms of intestinal indigestion. The course of the disease, while usually short, was prolonged in 8 cases. 3. As compared with summer diarrhea of other years, those in this series were in general much milder, owing possibly to the cool summer and increasing knowledge among the tenement class of the care of infants. 4. The marked number of breast-fed infants, 14 in 62 cases. Not one of these, however, was strikingly ill, and only 1 had blood in the stools. 5. The serum treatment was not given often enough to warrant conclusions. It may be that larger dosage is necessary; if so, the serum must be more concentrated. [H.M.]

2.—A Factor in the Etiology of Distorted Nasal Septums.—Charles E. Quimby states that while the condition of the distorted nasal septums may be produced by many agencies, he calls attention to one factor which he believes has been almost entirely neglected. That undeveloped and distorted septums are, in many cases, developmental defects, and require no other cause for their explanation. It has long been recognized that in many cases there is a difference in size and form of symmetric

parts of the facial skeleton; it has also been long observed that the narrow alveolar arch and asymmetric development are often most frequently associated with triangular teeth and varying grades of irregular dentition. It can therefore easily occur that the development of the facial skeleton is never perfect; failure in development is frequently so extreme as to prevent union of the 2 halves as shown in harelip and cleft palate. Therefore it hardly seems consistent for one to object to the proposition, that in some cases the superior maxillary bones unite at an unduly acute angle; that the vomer and the triangular cartilage, one or both, fail of proper articulation with the maxillary palate and ethmoid bones. From this point the production of deflected and distorted septums is merely a question of mechanics. [A.B.C.]

3.—Treatment of Gonorrhea in the Male.—Frederic Bierhoff lays great stress upon the prophylactic treatment of this condition. He states that prophylaxis is the ideal treatment. Haussmann, Kopp, and Blokusewski recommend the instillation of a few drops of a 2% solution of silver nitrate. Probably the greatest credit is due to Frank and Weland for their studies in the prevention of gonorrhea, by means of protargol solution. Both, working independently, succeeded in demonstrating conclusively that it is possible to prevent gonorrhea. Bierhoff has adopted the prophylactic measures in his practice, and recommends patients to instill 2 drops to 3 drops of a 10% to 20% solution of protargol in glycerin into the fossa navicularis, as soon as possible after the suspicious coitus. Thirty cases are reported, illustrating the statements which he sets forth. Various methods of prophylactic treatment are enumerated, with an enumeration of the important advantageous points in each. Basing his conclusions upon the comparatively few cases recited, they are as follows: Abortive treatment of gonorrhea is possible; if it be employed early, the percentage of cases in which a positive result may be obtained is fairly large; when one employs only those drugs which, while they kill the gonococci, do not injure the mucous membrane, the percentage of complications will be smaller than has heretofore been supposed; and should the attempt to abort the disease fail, the patient will not have been injured. [A.B.C.]

4.—Differential Diagnosis and Treatment of Chancroid and Chancre.—C. G. Clark says: A hard or syphilitic sore is generally small and insignificant. The edges are indurated, and its base is excavated and has a smooth floor with little or no secretion, while a soft sore may appear anywhere on the penis, is generally multiple and larger, its base being irregular and covered with a purulent discharge. In a chancre the incubation period is always more than a week and generally from 10 to 14 days. In a chancroid it is always less than a week and generally from 2 to 3 days. The inguinal glands are enlarged in both cases, but are much more apt to break down in chancroidal infection. In the syphilitic sore they are more shotty, uniformly enlarged on both sides, and do not break down as a rule. As the disease progresses the cervical and epitrochlear glands become enlarged. This never happens in chancroidal infection. In more than 1,000 cases of syphilis the author found in two-thirds the sore was on the corona and near the frenum. The best method of treating these cases is absolute cleanliness. Under no circumstances should the patient be put under antisyphilitic treatment until diagnosis be confirmed by the appearance of secondary symptoms. The old custom of burning every venereal sore with carbolic acid, nitric acid, and other corrosives only aids in delaying the healing process and making unsightly scars in many cases. [A.B.C.]

5.—Ocular Signs of Syphilis.—Wendell Reber states that no tissue of the eye or its appendages is free from the probable invasion of syphilis. What percentage of syphilitics exhibit ocular invasion it is unable to determine. DeWecker places the number at 15%. In 1,385 ophthalmic cases with a specific origin, Alexander found the ocular muscles infected in 15%, the uveal tract in 24%, and the optic nerve and retina in 48%. Syphilis in the visual sphere may assume any of the 4 usual phases, namely, primary, secondary, tertiary, and hereditary. The cases of iritis caused by syphilis is estimated at 50% by Brunson of Hot Springs. Choroiditis is as frequently syphilitic in origin as is iritis and it invariably leaves a scar in the choroid which is diagnostic years afterward. Nine German

observers found optic neuritis of syphilitic origin in 52½% of 981 cases; Alexander found 58% of 269 extraocular palsies to be syphilitic, while 77½% of intraocular palsies were from the same cause. Hereditary syphilis commonly affects the cornea in childhood and young adult life, though the ocular muscles may be involved, but interstitial keratitis is the form assumed most frequently by this phase of this disease. [A.B.C.]

6.—Syphilis of the Central Nervous System.—Luther C. Peter, in his paper, deals only with the immediate infection, the symptoms of which make their appearance usually from 6 months to 2 years after the initial lesion. He quotes Ayers' classification of the pathologic condition of brain syphilis as: (1) a localized meningitis leading to thickening and infiltration; (2) inflammation of the arteries leading to thrombosis; (3) gummatous deposits or tumors; and (4) degeneration of nerve structures. Paralysis of the cranial nerves, when there is no history of traumatism, is a factor in favor of syphilis. The fifth and seventh pairs are most apt to escape, whereas the sixth is usually involved. To sum up briefly, variability in symptoms, absence of systematic grouping of symptoms, paralysis of cranial nerves, 'Argyll-Robertson pupils, irregularity of pupillary margin, inequality of pupils, apoplecticiform and epileptiform attacks, recurrent palsies usually without loss of consciousness, numbness in extremities, increased reflexes, headache, vertigo, somnolence, and altered mental states, are symptoms which point to syphilis of the brain and its coverings. In syphilis of the cord we have a distinct group of symptoms, first described by Erb, characterized by a slowly oncoming spastic paraplegia, atrophic at times, contractures of the muscles, with involvement of the bladder; slight disturbance of sensation, with a tendency to improve and again relapse. [A.B.C.]

7.—Pharyngeal Lesions of Syphilis.—Lewis Somers calls attention to 3 important phases which a syphilitic lesion of the pharynx may present, viz.: Erythema, mucous patches, and ulceration. Syphilitic erythema is often mistaken for catarrhal pharyngitis or tonsillitis, but the erythema is usually symmetric, being limited in outline by abrupt, well-defined margins from the healthy mucosa; it differs from simple erythema, since it presents a deeper brick-red or more of a copper hue, and there is a marked tendency to the development of small irregular patches of cloudy swelling of the epithelium. When these areas of epithelial change become larger, well-defined and present a whitish or bluish-white color, they then constitute the so-called mucous patch. In ulcers the areas of tissue disintegration at first shallow, cover a wide, irregular surface and rapidly cause the soft tissues to melt away, while the affected parts are covered with a thick, mucopurulent, offensive secretion. The tendency to disintegration and perforation of bone is most marked, with but little or no pain. We should, if possible, obtain the history of the initial infection, examine other portions of the body for evidences of the disease and try the results of specific treatment. For the erythema and mucous patches mercury is essential. Syphilitic ulceration demands active treatment, as the tissue breakdown is rapid. Potassium iodid should be immediately pushed to the point of tolerance. [A.B.C.]

8.—New Stain for Diphtheria Bacilli.—E. Andrade refers to the failure of Löffler's blue at times to bring out the metachromatic granules. He prefers Borrel's blue, 1 cc. with vesuvin, watery solution 50 cc. The vesuvin should be dissolved in boiling water. In order that all other bacteria present may be decolorized, he uses Borrel's blue 5 minutes, washes in distilled water; uses Lugol's iodine solution 1 minute, washes in distilled water; decolorizes in absolute alcohol until no more blue is given off; washes in distilled water, dries, and mounts. [H.M.]

CLINICAL MEDICINE

DAVID RIESMAN

A. O. J. KELLY

REVIEW OF LITERATURE

The Bacteriologic Diagnosis of Diphtheria.—There is often an unmistakable discrepancy between the clinical and the bacteriologic diagnosis of diphtheria. The bacillus of Löffler

is often found in angina without membrane, and, on the other hand, it may be absent in membranous tonsillitis. Considerable difference of opinion prevails in consequence. B. N. Tcheruo-Schwarz¹ reports several cases of a puzzling nature and gives his conclusions in the following: 1. The bacteriologic method has proved beyond doubt that membranous angina, laryngitis, and croup may all be nondiphtheric in character. Many cases of laryngeal stenosis are on record in which no bacillus of Löffler has been found on repeated trials. Whenever, therefore, repeated examination fails to show diphtheria bacilli, we may safely regard the case as nondiphtheric. 2. On the other hand, the presence of Löffler bacilli is conclusive proof of diphtheria, provided the clinical picture corresponds to that disease. 3. If, however, the clinical picture contradicts the bacteriologic findings of diphtheria bacilli, we must remain in doubt until some new method will enable us not only to demonstrate the bacilli, but also to estimate the presence of systemic intoxication with the diphtheric poison. [L.J.]

Congenital Hypertrophy.—A case is reported by L. Cagiati.² At birth the parents of a child did not notice any deformity. But now, at the age of 11 months, the whole left side of the child has grown disproportionately to the right. The distance from the temporomaxillary articulation to the angle of the jaw on the right is 40 mm. (1½ in.); on the left is 60 mm. (2½ in.); length of left hand 100 mm. (4 in.); right hand, 85 mm. (3½ in.). From the coccyx to the right anterior superior spinous process of the ilium, 80 mm. (3½ in.); to the left, 90 mm. (3½ in.). The heart is normal in position, as are the abdominal viscera. No sense of smell can be proved. There is a slight choroiditis in left eye, whose eyeball is distended. The child is a female, of Hebrew parentage, and among none of the family can be found a history of lues, tuberculosis or nervous taint. Gestation in this instance was normal, and neither parent presents any distinct abnormality. [T.H.E.]

Diagnosis of Pulmonary Tuberculosis.—A Schmidt³ agrees with Naegeli that most all of us are tuberculous and that the cases are to be divided into the progressive and latent types, the latter again into active and inactive. This classification is suitable for the pathologist and the clinician, but he finds that our methods for the discovery of clinically latent cases, Koch's tuberculin, and the Arloing-Courmont serum test do not agree absolutely with limitations set by Naegeli. Our tests are often negative in markedly progressive cases, and frequently positive in individuals with thoroughly healed foci. Of the two, the tuberculin test is the more practical, not only because its results are more certain, but also because it is easier carried out; still it must be said that even it discovers too little in one line of the cases, too much in the other. The negative results of the tests are of much greater value than the positive. Because of this uncertainty in tests, it is no easier for the practitioner of today to determine whether prophylactic or therapeutic measures are necessary in the average latent case, than before. It occurs too frequently that, basing a diagnosis upon our uncertain methods, an individual is called tuberculous and his future marred for him by the fright thus produced; at other times through these wrong diagnoses an individual is put upon a pension, and thus needlessly pampered. Other symptoms which, in the hands of the inexperienced, are likely to lead to wrong diagnoses are: 1. Irregular configuration of the shoulder girdle may lead to simulation of dullness and retraction of the apex. He relates cases of scoliosis, atrophy of isolated muscles and abnormally high position of scapula, in which because of dullness about the apical area tuberculosis was needlessly diagnosed. 2. Hemorrhage from small bronchiectatic foci; a typical case of pseudotuberculosis is quoted in a man of 35. 3. Pseudorales and friction sounds heard at the margin of the lungs, especially in scoliotic subjects. He thinks that infinitely more harm is done by needlessly frightening persons with the announcement that they have tuberculosis than would result from overlooking of a few cases that later proved to be actually progressing tuberculosis. [E.L.]

GENERAL SURGERY

MARTIN B. TINKER

A. B. CRAIG

C. A. ORR

REVIEW OF LITERATURE

The Surgical Treatment of Epilepsy.—J. Chalmers Da Costa¹ says that an opinion regarding this subject, to be of value, must emanate from one who possesses a scientific knowledge of epilepsy, who has studied the particular case with painstaking care, and who has a surgical conscience. The great difficulty in the surgical treatment of epilepsy is that the pathology usually assigned to that disease is a probability or a guess instead of an established certainty. Epilepsy, from the surgical standpoint, is classified in 7 varieties, each of these being discussed separately. The conclusions are: Operations for epilepsy are distinctly disappointing and rarely curative and are indicated in only a small proportion of cases; they frequently produce temporary benefit; they may save life but are not entirely free from danger and occasionally leave the patient worse than before; the mortality, though small, is not inconsiderable; the actual number of complete recoveries is probably under 5%; no case should be claimed to have been cured until from 3 to 5 years have elapsed after the operation; even after operation, medical treatment and supervision should be exercised for a long period of time. [A.G.E.]

Surgery of the Lung.—Valerio and De Fabii² discuss procedures of value after trauma. The former gives results of many experiments on dogs. One great source of danger is the development of a pneumothorax, which occurs as a sequel to operation. This is overcome by mobilization of the region of operation, and by an arrangement whereby hernia of the adjacent lung tissue occurs; this occludes the orifice and lessens the possibility of a communication being established between the pleural cavity and the external air. The suture advised in lung tissue is modeled after that in enterorrhaphy. When it is not practicable to suture, Valerio suggests the production of hemostasis by minute particles of decalcified bone. It is probable that wounds of the lung tend to spontaneous recovery, whatever their nature, and that the microbic flora of the lung is of little influence in causing traumatic infection when that occurs. Hemothorax predisposes to a pneumopleuritis. In any instance, avoid operation when possible. [T.H.E.]

Hammer-finger, with Notes of 7 Cases Occurring in One Family.—J. Scott³ thinks if hammer-finger were oftener recognized at an early stage there would be a much better chance of curing the deformity without surgical interference. In the family reported, contraction occurred during the developmental period. Probably it is sometimes congenital. It is often hereditary. The structures affected are the ligaments, bone, flexor tendon, skin, and fascia. The bone deformity is the primary lesion. Treatment consists in practising forcible extension of the affected fingers frequently, and wearing at night a splint of metal covered with leather, shaped to fit the palm, with divisions corresponding to the affected fingers, and fixed at the wrist by a strap. The fingers are straightened as much as possible by bandaging to the metal prolongations. This failing, surgical treatment is indicated. [H.M.]

TREATMENT

SOLOMON SOLIS COHEN

L. F. APPLEMAN

E. LINDAUER

REVIEW OF LITERATURE

Injection of Saline Solution followed by Death.—Ch. Achard and G. Paiseau⁴ point out that saline injections are used for 2 purposes—to make up for the loss of volume of the blood in severe hemorrhage and to increase the renal elimination of noxious substances (*lavage du sang*). The second object is attained only when the injection is quickly followed by abundant diuresis—a result which does not always follow even in experiments on animals. When this diuresis fails,

symptoms, notably dyspnea, may be induced both in man and animals. Achard has in conjunction with Laubry shown that the diuretic effect is habitually absent in the subjects of chlorid retention, a frequent condition among patients. This absence of diuresis is a direct consequence of the chlorid retention and in such cases, saline injections, like simple ingestion of salt, may produce serious results—increased of pathologic effusions, dyspnea, uremia, and even death. Further, large injections are dangerous not only on account of the salt they contain; the water itself may by its abundance produce ill effects.—[*Medical Review*, February, 1904.] [Much is yet to be learned concerning the right composition and right use of saline injections and every scientific contribution to the subject is of importance. S.S.C.]

Schools and Exercise.—Conscious attention to the muscular exercise of children has been made necessary by the growth in school population, and the increase in the length of time during which children go to school. Gulick¹ states that in 1840, out of a total population of 17,069,453, in the United States, there was a school population of 2,025,565, or 11%. In 1890, out of a total population of 62,622,250, there was a school population of 14,768,965, or 23%. The normal life of the child is one of steady activity during the waking hours. We are taking away for 5 hours a day a large part of this activity. Exercise is fundamentally related to growth, so that the decrease of exercise by school life during the early years of the individual's life is of great importance. Not only is muscular exercise decreased by school life, but pressure is brought to bear to increase the attention to psychic things. Thus, there is a coincident decrease in muscular expenditure and an increase in lines that are purely neural. The remedy lies in greater attention to play, especially out of doors, and in appropriate gymnastic exercises; not however showy calisthenic drills which are nervously fatiguing and of little value as exercise.

PATHOLOGY.

J. EDWIN SWEET

EDITORIAL COMMENT

The "Ultramicroscopic" Organisms of Disease.—Evidence is constantly accumulating that there is a distinct group of diseases caused by organisms too small to be detected by our most powerful microscopes. This evidence has been obtained by experiments with porcelain filters, the pores of which are so small as to prevent the passage of bodies measuring 0.1 micron in diameter—which dimensions represent the optic limit of our best instruments. We have already called attention in these columns to the conclusion of the French yellow fever commission² that the virus of yellow fever will pass through a porcelain filter. The same conclusion has also been reached from experiments with the peripneumonia of cattle, with sheeppox, and possibly most important among others, with rabies. Remlinger³ describes the results of his work in regard to the action of porcelain filters upon the virus of rabies. Several workers have already performed such experiments, and have found that the etiologic factor would not pass the filter; Remlinger believes that the reason for these negative results is that these experimenters used filters with too fine pores. He has, therefore, experimented with the Berkefeld "V," a filter with comparatively large pores, yet with pores so small that organisms so small as those of chicken cholera and water organisms, still smaller, are held back. About 30% of the subdural inoculations with the filtered emulsion of the brain of an animal dead with rabies gave positive results. The subcutaneous injection of increasing amounts of this filtrate conferred an immunity, a point so far as we know not proved by other workers, yet of great importance regarding the passage through the filter of the etiologic factor of rabies. The conclusion seems justified that

¹ *Medicine*, February, 1904.² *Il Policlinico* (Rome), No. 7, 1904.³ *Glasgow Medical Journal*, November, 1903.⁴ *Bulletins de la Soc. Méd. des Hôpitaux*, December 4, p. 1362.¹ Cohen's System of Physiologic Therapeutics, Vol. VII.² *Annals of the Pasteur Institute*, November, 1903.³ *Annals of the Pasteur Institute*, December, 1903.

rabies is caused by some one of the group of ultramicroscopic organisms. Advance in medicine is always dependent upon advance in general knowledge. Now it seems that medicine must wait for the physicists to devise some improvement in our optical instruments.

Hodgkin's Disease.—The clinical entity marked by progressive enlargement of the lymph-glands, anemia, and sometimes an increase in the number of the white cells, with the secondary symptoms which may be caused by these conditions, and known as Hodgkin's disease, has not until very recently been thoroughly studied; tuberculous lymph-adenitis has been most generally confused both clinically and pathologically with true Hodgkin's disease. A very careful paper by Longcope¹ gives us a clear and complete study of eight cases of this disease. Longcope's paper confirms and completes the work of Reed,² and the results of both these workers are confirmed by the work of Simmons.³ The results of these three papers may be summarized as follows: The disease is definite and distinct, originating in the lymphatic tissue; this tissue and the newly formed lymph-glands at first simply increase in size, then follows a proliferation of endothelioid cells, formation of giant cells, thickening of the reticulum, and finally, overgrowth of connective tissue. Eosinophiles are abundant, but are not specific. The tubercle bacillus plays no part in the production of the lesions. The etiology is thus far unknown, but Longcope makes the very pertinent suggestion that Flexner's work on the specific toxins for lymphatic tissue may contain an explanation for Hodgkin's disease—that some specific toxic substance of bacterial or cellular origin causes the peculiar proliferative changes in the lymphatic tissue.

REVIEW OF LITERATURE

Anatomic Study of the Human Parathyroid Gland.—H. Petersen⁴ comprises a careful histologic study of these small organs, which are of late attracting considerable attention, and which from their importance in the animal economy and the lack of definite knowledge concerning their function, are to be ranked with the adrenals and the pituitary body. The study covers an examination of 100 cases, and details the gross and microscopic character of the organs; the structure of the parathyroid resembles markedly that of the adrenals. The glands seem quite subject to degenerative changes, 67 of these 100 cases showing parenchymatous swelling, formation of colloid or of cysts, and general overgrowth of fat tissue.

Experimental Studies of Air Embolus.—L. P. Wolf⁴ gives a very complete bibliography of this much mooted question, and concludes from his experiments that death is due to embolism of the capillaries of the lungs, and not due to the filling of the heart with air, as is generally accepted and taught.

Formation of Pigment and Organization, Especially in an Extradural Hematoma.—R. Milner⁴ discusses the changes which occur in the breaking up of the hemoglobin in extravasates of blood; the cause of the chemic changes in the surrounding tissue; leukocytes have little influence upon the formation of pigment. Details, methods, and literature are discussed at length.

Etiology and Pathogenesis of Black Water Fever.—A. Plehn,⁴ beside a discussion of the pathology of cases of this chiefly tropic disease, reaches the following conclusion of general interest: In 24 of 168 cases, quinin had either not been given or not recently enough to be considered the cause. The disease may follow the administration of other drugs, such as salipyrin, phenacetin, and methylene-blue. The development and the disposition of black water fever depends upon the activity and number of those latent forms of the malarial parasite, which continue the infection during the periods between the attacks of fever and after the primary inoculation, concerning which forms, nothing is known. It would seem from this

paper that the extensive destruction of erythrocytes, characterizing black water fever, is due to an accumulation of the toxic products of the plasmodiums, and possibly that quinin by its specific action in destroying the plasmodiums, may suddenly set these toxic products free in unusual quantity.

The Pathologic Anatomy of Whoopingcough and the Presence of the Whoopingcough Bacilli in the Organs.—G. Arnheim¹ obtained his results from a study of 8 autopsies. Whoopingcough is an infectious, frequently desquamating catarrh of the mucous membrane of the respiratory tract, especially of the trachea; the characteristic bacillus is found often in masses in the secretion, in the mucous membrane, and in the bronchial pneumonic areas, where the lung is affected. The cough is caused by the presence of colonies of bacteria at the typical "cough regions." The secretion becomes viscous in the course of the disease, probably due to the increased chemotactic influence of the secondary infection with pyogenic organisms. The paroxysms of coughing are to be considered a healing process by mechanically removing the specific bacteria.

Carcinomas of the Gall Ducts and Adenomas and Primary Cancers of the Liver Cells.—V. Fisher¹ describes 3 cases under the above heading, with a view of establishing his belief that the majority of cases described as carcinomas arising from the liver cells were really primary tumors of the gall ducts; carcinoma cylindrocylindricum gelatinosum oesophagi, an addition to the teaching of fetal inclusion. Franke³ describes a tumor of the esophagus, situated a short distance from the cardia, which he concludes could only have arisen from dislocated cylindric cells of the mucous membrane of the stomach.

The Coagulation of the Blood.—J. Bordet and O. Gengou² describe very interesting experiments upon the coagulation of blood plasma, the most important results of which are that coagulation occurs independently of any formed elements such as leukocytes or blood-plates, and the confirmation of the role of the calcium salts in coagulation, first described by Pechelharing.

Experimental Studies of Syphilis.—El. Metchnikoff and Em. Roux² report the successful inoculation of syphilis into chimpanzees; the disease presented a typical characteristic course. The experiments are being continued and a further report is promised.

Anaerobic Organisms and Symbiosis.—Bienstock² has studied the phenomenon first described by Pasteur, that many of the most strict anaerobes can flourish in the presence of oxygen when growing with some aerobic organism. He has worked principally with a bacillus which putrefies fibrin. The most interesting and suggestive conclusion reached is that the ferment produced by *Bacillus pyocyaneus*, called by Emmerich and Löw "pyocyanase," has the same property as a growing aerobic organism of furthering the growth of a strict anaerobe. Pasteur's idea that this symbiotic phenomenon is due to the extraction of oxygen from the medium by the aerobic organism seems therefore to be inadequate to meet all the conditions of symbiosis.

The Pathologic Anatomy of "Paratyphoid Fever."—H. G. Wells and L. O. Scott² give a description of autopsy findings in a fatal case of paratyphoid fever and a thorough review of the literature upon the subject. This disease can hardly be distinguished clinically from typhoid, except in its usual mild course and by the agglutination reactions. The cause is supposed to be an organism which stands midway between the typhoid and the colon bacillus. This case is the fifth with autopsy report. The summary of the pathologic findings as given in this paper seems to confirm the result of the agglutination reaction—that "paratyphoid" is in its pathology different from ordinary typhoid; the anatomic changes are simply those of septicemia with splenic swelling, and occasionally nonspecific ulcers in the intestine. The ulcers in the 3 cases reported resemble those of dysentery rather than those of typhoid; there is no alteration of Peyer's patches nor of the solitary follicles.

The Embryoid Tumors of the Sex Glands, and the Presence in These Tumors of Growths Similar to Chorion-

epithelioma.—H. Steinert¹ discusses at length the theory of these tumors, and gives a fair bibliography. The tumor described was from the testicle, belonging to the group classed by Wilms as "embryoid" tumors. Steinert points out the difficulties which confront a rational explanation of such forms, but adds little new. [J.E.S.]

Chorioepitheliomas Originating Beyond the Confines of the Placenta.—O. Busse¹ describes 2 cases of this class of tumors, which have always excited the interest of pathologists. The cases were marked by the fact that no sign of tumor formation could be found at the site of the placenta. Both instances offer the typical picture of a very malignant tumor, with metastases carried by way of the circulation; in 1 case the primary tumor seemed to be in the left ventricle, in the second case in the parametrium. The uterus in both cases showed the changes characteristic of both extrauterine pregnancy, and of the few cases of this tumor formation which have been recorded. [J.E.S.]

The Formation of Adenomas and Carcinomas from the Ampulla of Gärtner's Canal.—R. Meyer¹ divides this paper into 2 parts, the first discussing the position of Gärtner's canal, anatomically and embryologically; at an early stage an ampulla can be demonstrated, which is often provided with gland-like structures. The second part discusses a case, which Meyer believes represents the first described case of a carcinoma arising from this ampulla of Gärtner's canal. The case presents the further interesting complication of tuberculosis of the mucous membrane of the cervix. [J.E.S.]

An Addition to the Question of the Genesis of the Blood-platelets.—P. Schneider¹ gives an extensive discussion of the literature upon the subject of the platelets, the methods in use, and experiments which led to the result that the blood-plates are not independent cells, but are cell derivatives. The great majority of the plates of normal blood come from the red cells, while others may possibly come from the white cells. Most of them possess nucleus substance, which can be demonstrated by stains, and which is the cause of the resistance of the plates to diluted acetic acid. [J.E.S.]

Blood-platelets Differentiated through Staining.—K. Preisch and P. Heim² have succeeded in staining blood-plates so that different portions may be differentiated. They were able to demonstrate nuclei and granules; the method they used is a modification of the Romanowsky method. As they found the platelets often inside red corpuscles, they believe them to be a nucleated formation of the red cells, which is by it extruded into the circulatory stream. Their occurrence within leukocytes must be explained by the process of phagocytosis. It is possible that the granules of leukocytes are simply granulations of phagocytized platelets, especially as they correspond with them in size, staining reaction, and other points. [E.L.]

Pathologic Histology of Hodgkin's Disease.—W. T. Longcope³ reports the pathologic findings in 8 cases of Hodgkin's disease, giving in detail the histology of the involved structures. The results of this careful study occupy some 75 pages, in addition to which are a number of illustrative plates. We can give here only the conclusions of the report, which are: (1) Hodgkin's disease should be considered as a distinct clinical and pathologic entity; (2) the lesions in the lymph-glands and other organs are especially characterized by the early increase in the lymphadenoid tissue, with later proliferation of endothelioid cells, formation of uninnuclear and multinuclear giant cells, thickening of the reticulum, and finally overgrowth of connective tissue. Eosinophiles, though not specific, are frequently found in great abundance. Together with the abundance of eosinophiles in the lymph-glands, the eosinophilic leukocytes and myelocytes of the bone marrow are increased; (3) the process originates in lymphoid tissue, and during the course of the disease there are constantly being formed new lymph-glands, which ultimately become the seats of the lymphomatous growths; (4) in rare instances the retro-

peritoneal lymph-glands may be the only group affected; (5) the etiology of Hodgkin's disease is so far unknown. The tubercle bacillus plays no part in the production of the lesions. [A.G.E.]

The Bacillus of Turtle Tuberculosis.—F. F. Friedmann¹ found that the second generation of cultures of turtle tuberculosis bacilli, when growing at 37° C. on glycerin agar could not be distinguished from bovine or human tubercle bacilli. It therefore differs from all tubercle bacilli thus far cultivated from cold-blooded animals. When this bacillus was injected into guineapigs, in not too large doses, typical tuberculous processes developed, but they remained localized invariably and showed a tendency to heal, thus supporting Koch's theory of the quality of the different species of tubercle bacilli, and especially of the human and bovine types. [E.L.]

The Bacteriologic Postmortem Diagnosis of Plague.—The bacteriology of the bubonic plague is sufficiently developed to allow a diagnosis to be made without much difficulty on fresh bodies. Far more difficult is the recognition on decomposing bodies, due to the rapid destruction of the bacilli. S. T. Goldberg² offers a number of guiding principles: 1. It is necessary to resort to direct infection of the animals from the dead body to be tested. The best adapted animal for the purpose is the guineapig. 2. In the case of fresh bodies, an emulsion of the material to be tested may be injected beneath the skin of the animal or into its peritoneal cavity; when the body is decomposed, however, the animal should be infected on the nasal mucous membrane. 3. Low temperatures favor the preservation of the bacilli in the dead body. Rapid and marked changes of temperature have an opposite effect. 4. The bacilli are best preserved in the buboes of the disease, and these should in all difficult cases be the source of animal infection. [L.J.]

Diagnostic Value of Cytologic Tests of Effusions.—A. Signorelli³ shows the method of determining same, and his conclusions are: In effusions of serous character there is a cellular reaction, both general and local in origin. The proportion of polynuclear cells is the exponent of phlogistic, or sthenic and general, acute reaction. The lymphocytes are indicative of local inflammatory processes, subacute or chronic even, and relating to the serous membrane or its underlying structures, in reorganization. There is a pseudolymphocytosis to be distinguished. Here embryonal or unstable organisms point to a breaking down, or retrogression. Of diagnostic importance is history of rapid or slow lymphocytosis, and the gradual or sudden disappearance of the same; while recrudescence of the morbid process is foreshadowed plainly by changes in character and number of the cellular fluid-constituents. The writer cannot agree with those who claim to differentiate exudates and transudates. [T.H.E.]

Tetanus and Vaccine Virus.—J. H. Huddleston⁴ reports the results of a series of experiments made upon calves supplied to the Vaccine Laboratory of the New York City Health Department. In the feces of two out of twenty-five that had been fed with hay, tetanus bacilli were found. Numerous experiments tending to show the action of tetanus bacilli when mixed with virus were made with the following results: (1) Tetanus germs do not develop in glycerinated virus; (2) if any form of vaccine virus, either dry points or tubes of glycerinated virus, is infected with tetanus, it may convey it; (3) small amounts of the tetanus infection easily fail of demonstration, both by animal and by cultural tests; (4) if tetanus germs are applied in quantity to the inoculated areas of a calf at any time during the period of vaccine production the tetanus may be present in the vaccine virus collected; (5) inoculation by scarification is a possible method of inducing tetanus in susceptible animals; (6) it is probable that precaution against the issue of infected vaccine virus consists less in tests of the virus than in care taken during production, and especially in the cleanliness of the methods in use in the stable and in the laboratory. [A.G.E.]

Pathology of the Ductus Arteriosus.—O. Wagener⁵ reports 2 cases of patulous ductus arteriosus, which corre-

spond in many points. At the pulmonary end in each case there was an occluding membrane, which bulged into the pulmonary artery. In the first case this membrane formed a complete separation between the contents of the duct and the pulmonary artery; in the second case there was direct communication by means of perforations in the membrane. No cause could be determined for the persistence of the duct in either case. Above the aortic opening of the duct in both cases there was a ridge-like projection into the lumen of the aorta; in the second case it formed a sort of funnel-shaped opening into the duct. The author believes that the occluding membrane at the pulmonary end was of recent origin in both cases, and claims that the duct may be completely patulous throughout life, without giving rise to symptoms. [B.K.]

Immunization of Man with Diphtheric Toxin.—W. N. Boldirew¹ reports on some highly interesting experiments of his own, made with a view of immunizing the human organism against diphtheria. It has been noted that horses employed in the production of diphtheria antitoxin retain their acquired immunity for a number of years. This suggested the idea of immunizing human beings in a manner very similar in principle to vaccination. Such an attempt has been made by Dzerzowsky, who injected into himself 4,300 minimal fatal doses of diphtheria toxin (fatal to guineapigs!). As a result the quantity of antitoxin in his blood rose to 1 unit (according to Behring) in 1 cc. of the serum. This experiment conclusively proved the possibility of human immunization against diphtheria. The author now took up these experiments and made on himself a series of injections with small quantities of toxin. He found that even minute doses of toxin (5 minimal fatal units to guineapigs) resulted in the production of considerable amounts of antitoxin (at least 600 units). This net result ought to encourage further research. The author thinks that at present too much attention is absorbed by serum treatment, while active immunization with toxins is neglected. However, Behring's recent report on immunity in tuberculosis is a step in advance. [L.J.]

A Clinical Test for Urobilin.—To prove the presence of urobilin, W. Schlesinger² adds to the urine an equal quantity of an alcoholic 10% solution of zinc acetate; the precipitate is filtered out. Even though the urine contains but a small quantity of urobilin and a large quantity of other coloring matter, a beautiful fluorescence and distinct spectrum bands will be obtained. Hemoglobin always disturbs the reaction, and even intense urobilinuria will not be recognized if blood be present. To overcome this fault, he has modified the test by adding potassium oxalate in normal salt solution, which prevents the coagulation of the blood and permits the removal of the red corpuscles by centrifugation, leaving the clear blood plasma behind. [E.L.]

Bacillus Tuberculosis in Man and Animals.—M. P. Ravenel³ presents the report, signed by E. A. deSchweinitz and Veranus A. Moore, of the committee of the laboratory section of the American Public Health Association on *B. tuberculosis* in man and animals. Reference is made to the experiments and clinical observations of a number of writers. The report concludes as follows: In summing up the available evidence, we feel that there is strong ground for believing in the genetic unity as well as the intertransmissibility of the human and bovine races of the tubercle bacillus; we consider that it has been positively proved that a certain proportion of persons, chiefly young children, meet their death through infection with the bovine tubercle bacillus, but the knowledge at hand does not enable us at present to define the extent of this danger. [A.G.E.]

Serous Exudate or Transudate; Differential Diagnosis.—The clinical meaning and histochemic examination of 27 selected cases is reported by Agenor Zeri,⁴ who emphasizes the importance of careful microscopy in early diagnosis. The serous fluid extracted from the patient is exudative, transudative, or normal. Its specific gravity, the nature and quantity of contained albumen, extracted matter, toxins, or globulicides should be considered. Coagulability and presence of micro-

organisms noticed. Cryoscopic tests. Contrasts are observed among transudates in peritoneal cavity from hepatic syphilis, hepatic atrophy, and tuberculous peritoneal exudates; pleural effusion, and pleural transudates due to pulmonary tumor, or cardiac lesion. The cerebrospinal fluid is highly indicative of the nature of adjacent morbid processes. All serous effusions are diagnostic in regard to the various elements contained. The microscope will show predominating, wandering, partially disorganized nuclei; large and small leukocytes, vacuolated or not, single or multinuclear cells; eosinophiles, basophiles, or others. The differences may thus be early drawn among lesions of syphilitic, tuberculous, or alcoholic causation. [T.H.E.]

The Action of Elasticity on Microbes.—S. M. Burak¹ reports his experiments in this direction. He finds that electricity is inimical to bacterial life. The constant current may produce complete and permanent changes of the specific type of microorganism, while the faradic current does not leave much lasting changes, although its action for the time being is more energetic. By means of successively influencing several generations of bacteria, the usual type of their functional life may be radically altered, and microbes thus affected produce a new generation which is still more susceptible to the electric current. The action of electricity is stronger when the nutritive conditions are poor. The morphologic characteristics of microbes are not altered, but only their physiologic activity, especially motility, while growth is very little influenced. During the electric influence the development of bacteria is retarded, and their duration of life is subsequently shortened. By means of very frequent and high currents it will perhaps become possible to act on bacteria even within the animal body. [L.J.]

Physiologic Action and Antidotes of Snake Venom.—Leonard Rogers² discusses antidotes to the viperine and colubrine snake venoms. Calmette's antivenene has no efficiency against the viperine venoms. He mentions potassium permanganate which Wynter Blyth first showed would rapidly destroy the power of cobra venom, when mixed with it *in vitro*. Experiments made by Burton and Prayer showed that strong solutions of this substance injected at the seat of the insertion of the poison did not prove successful. They later suggested that a ligature be placed around the limb and that the pure crystals of potassium permanganate moistened with a little fluid be rubbed in through an incision made at the point where the reptile's fangs had entered. The author has carried out a preliminary series of experiments along these lines with the most promising results. In short it consisted of various experiments made upon cats and rabbits into which had been injected not only lethal, but in numerous instances many times the lethal dose of snake venom. In every instance in which the dose received was not more than could be expected from a single bite of the reptile the life of the cat was preserved. Rabbits were more easily killed than cats. In instances in which the potassium permanganate was rubbed in $\frac{1}{2}$ m. after 10 times, 5 m. after 5 times the lethal dose, and 10 m. after 3 times the lethal dose was injected, the cats' lives were saved. Thus it is certain that a very small amount of this drug will neutralize, by actual contact, a lethal dose of snake poison for man. [A.B.C.]

Examinations Concerning Streptococci.—H. Arenson³ has always been of the opinion that there are no specific differences between the streptococci of different diseases, as any streptococci may produce⁴ articular or cardiac lesions in the horse, and as the serum of a horse immunized with a definite culture protects against all streptococci and agglutinates any of them. These examinations referred to cultures which had been made highly virulent for horses by previous passage through mice and rabbits. To prove that streptococcic cultures cannot be differentiated from each other by the agglutination test, as has been claimed by others, he experimented with 27 different cultures without previous intensification, and reports the following results: Even using the most delicate biologic methods, he was unable to separate the various varieties of

human streptococci. Microscopic examination, culture tests, agglutination methods and immunization failed him in determining the origin of the streptococcal culture. On that account he insists that the streptococci cannot be considered as the cause of a typical and peculiar infectious disease as scarlet fever is, but must insist instead that all its serious complications are due to it. It cannot, therefore, give a specific scarlet fever serum, but must consider any streptococcal serum to be an active agent in the disease. He intends to add to his serum, which is drawn from horses immunized with different and highly virulent cultures, a serum from a horse immunized with streptococcal cultures taken directly from man. [E.L.]

A New Method of Serum-diagnosis.—G. N. Kasarinoff¹ publishes his experience with Ficker's new method of diagnosing typhoid fever. The idea was to obtain an extract from dead typhoid bacilli, as living cultures are impracticable outside of laboratories. Ficker has succeeded in preparing an emulsion of dead bacilli, thus enlarging the field of Widal's reaction considerably. Our author reports favorably on the new method, considering it equal in reliability to Widal's test. [L.J.]
